23 **Abstract**
24

25 This study examined the developmental trajectories associated with response
26 inhibition and error processing as exemplar executive processes. We present fMRI data
27 showing developmental changes to the functional networks underlying response
28 inhibition and error-monitoring, comparing activation between adults and young
29 adolescents performing the Sustained Attention to Response Task (SART). During
30 successful inhibitions, we observed greater activation for the young adolescents than for
31 the adults, in a widely distributed network including frontal, parietal and medial regions.
32 When inhibition failed, however, adults showed increased activation compared to young
33 adolescents in a number of regions, including bilateral parahippocampal gyrus, left and
34 right lingual gyri, the right insula, and cerebellar regions. These differences largely
35 remained even when the two groups were matched for performance, suggesting that
36 performance differences are unlikely to be the driving factor behind these developmental
37 differences. Instead, the neurodevelopmental trajectory of these important executive
38 functions may reveal the basis for the immature executive functioning of the young
39 adolescent.

Introduction

Response inhibition, or the ability to withhold a prepotent response, is a key aspect of executive functioning, allowing us to operate in complex situations with competing stimuli that demand our attention. The dynamic control of behaviour in these situations involves a number of distinct functions, including task-monitoring, error-detection and compensatory changes to behaviour after an error has been detected. Areas involved in these functions include a number of prefrontal regions such as the anterior cingulate cortex (ACC) and dorsolateral prefrontal cortex (DLPFC) (Dehaene et al., 1994; Garavan et al., 2002). Response inhibition may be one of the first executive functions to develop, with early forms of error monitoring, self-regulation of behaviour and response inhibition having been observed in children as young as 4 years old (Jones et al., 2003). Whereas some cognitive processes, such as attentional orienting, develop early and show little change between childhood and adulthood, the ongoing development of executive functions, such as response inhibition, differentiates childhood cognition from that of adulthood (Denckla, 1996). This development may occur in parallel with sequential maturation of the frontal lobes (including myelinisation, synaptic pruning and reorganisation, dendritic and axonal arborisation), which is not completed until early adulthood (Anderson et al., 2001; Gogtay et al., 2004).

Response inhibition is often measured using Go/No-Go paradigms where participants are asked to make a simple response (e.g. pressing a button) to the majority of stimuli, but to withhold this response to an infrequent (and usually unpredictable) target (No-Go) stimulus. In the current study we used the Sustained Attention to Response Test (SART), a Go/No-Go task which has previously been used to investigate 'attentional slips' in everyday life (Robertson et al., 1997), as well as to investigate response inhibition in a number of clinical conditions, such as Traumatic Brain Injury (TBI) (McAvinue, O'Keefe, McMackin, & Robertson, 2005; but also see Whyte et al., 2006), attention deficit hyperactivity disorder (ADHD) (Johnson et al., 2007a), high-functioning autism (Johnson et al., 2007a), schizophrenia (Chan et al., 2004), and sleep disorders (Fronczek, Middelkoop, van Dijk, & Lammers, 2006).

1
2
3 Successful inhibition on the SART task elicits the classic No-Go N2/P3 complex
4 which is a robust electrophysiological marker of inhibitory control. (O'Connell et al,
5 2008).
6
7

8 In an fMRI study of healthy adults (Fassbender et al., 2004), successful
9 inhibitions on the SART increased activity in the right ventral frontal cortex, left DLPFC,
10 the right inferior parietal lobe (IPL), as well as the left putamen, consistent with other
11 studies showing a network of prefrontal and parietal regions involved in response
12 inhibition (e.g. Garavan et al., 1999; Rubia et al, 2007; Stevens et al., 2007). For
13 commission errors (responding to the No-Go stimulus), which may involve processes
14 related to (late attempts at) response inhibition and error-detection, increased activation
15 was observed in the anterior (ACC) and posterior cingulate (PCC) cortex, bilateral
16 inferior frontal gyri (IFG) and insulae, and (predominantly left) inferior parietal regions.
17
18
19
20
21
22
23

24 In the current study, we compared SART performance of adults and young
25 adolescents to understand further the development of inhibitory control and its associated
26 neural networks. To avoid performance differences between the two groups confounding
27 the activation maps (see Murphy & Garavan, 2004), we used an event-related design
28 which allows direct comparisons of successful and unsuccessful inhibitions. Although
29 more recent studies (Rubia et al., 2006; 2007; also see Bunge et al., 2002) comparing
30 response inhibition between adults and adolescents suggest increased activation of frontal
31 and prefrontal regions in adults, earlier studies (Booth et al., 2003; Casey et al., 1997;
32 Durston et al., 2002) showed the reverse pattern. A recent longitudinal study (Durston et
33 al., 2006) showed activity in the right inferior frontal gyrus increased with age, whereas
34 activity in most other regions (including precentral, superior frontal, superior temporal,
35 and posterior cingulate gyri) decreased with age. It has been suggested (Rubia et al.,
36 2006) that differences between these studies may be due to factors such as sample size
37 (which were relatively small in the earlier studies), or differences in age range (under 12
38 in the earlier studies, compared with adolescents aged between 10-17 years in the studies
39 by Rubia et al.), or because some earlier studies used block rather than event-related
40 designs (Booth et al., 2003). Differences between the specific paradigms used, however,
41 especially when these may engage processes other than response inhibition, might also be
42 a confounding factor. For example, the tasks used by Rubia and colleagues (2006; 2007)

1
2
3 and by Bunge and colleagues (2002) also have a strong spatial component, in addition to
4 engaging processes related to response selection, as participants had to choose between
5 different responses depending on the spatial configuration of the stimuli. The SART,
6 however, only requires participants to make a single type of response to unambiguous
7 and pre-specified Go stimuli (all digits bar “3;” see task description below) or to withhold
8 this response and thus may avoid contamination from other cognitive processes (see also
9 the paradigm used by Durston and colleagues (2002; 2006)).

10
11
12
13
14
15 The studies by Rubia and colleagues (2002; 2006) also differ in one other
16 important aspect from the earlier work: whether or not the adult and adolescent groups
17 performed tasks that were equated for difficulty in terms of stimulus properties (e.g.,
18 similar timings) or in terms of performance (e.g., by using an adaptive staircase
19 mechanism that ensured performance at a criterion level). There are good arguments for
20 using either method. The first, in which task properties are held constant, avoids
21 confounding age/ability with differences in the objective difficulty-level of a task. The
22 second method ensures that everyone performs at the same level of performance, thus
23 avoiding confounding age/ability with processes secondary to performance such as error-
24 related frustration. The choice of method may be consequential with one hypothesis
25 being that equating task-difficulty may reveal greater levels of activation in young
26 adolescents (on account of their poorer inhibitory abilities requiring more neural
27 resources be deployed than are required by adults). On the other hand, equating
28 performance levels may reveal greater levels of activation in adults (their superior
29 inhibitory abilities may result in more neural resources being accessible for adults
30 relative to those that are available for young adolescents). To disentangle the influence of
31 ability and performance from inherent age-related differences, the present study
32 employed a task at a set level of difficulty but also included a performance-matched
33 analysis of a subset of adult and young adolescent participants

In addition to activation during successful inhibitions, we also examined activation associated with unsuccessful inhibitions (commission errors). Here activation can be assumed to include processes related to error-detection and increased top-down

1
2
3 attentional operation¹ (Garavan et al, 2002). Rubia and colleagues (2007) found increased
4 activation of rostral ACC for adults compared to children/adolescents in a design that
5 matched performance between the two age-groups, and this has also been observed
6 without performance matching (Velanova et al., 2008). To our knowledge the studies by
7 Rubia and colleagues and by Velanova and colleagues are the only other developmental
8 imaging studies to examine error activity during response inhibition. Accordingly, we
9 predicted a similar pattern of activation differences between the adults and young
10 adolescents in the current study.

Forty right-handed participants, 20 young adolescents (all males) in the age range 10-14 (mean age 12.4, SD 1.4) and 20 adults (15 male) in the age range 23-35 (mean age 26.8, SD 4) were involved in this study. A subset of this sample with matched performance was subsequently selected to assess the impact of performance on activation patterns. The subsample consisted of 12 young adolescents (all male, mean age 12.7, SD 1.3) and 12 adults (including three females, mean age 25.5, SD 3.5). To ensure that this gender imbalance in the full sample did not unduly affect the results, we also report analyses using only the data from male participants.

The study was approved by the local ethics committee in accordance with the Declaration of Helsinki. All participants were reported (by themselves and/or a parent) to be free of neurological and psychiatric disorders and head trauma, and gave written consent to participate (for the young adolescents, written consent was also given by a parent).

¹ Activation changes during error trials may be related to other processes, including late attempts at inhibition, momentary lapses of attention, or increased maintenance of the go-rule. These additional processes are likely to fluctuate across trials (i.e. for any given error trial, the error might be caused by a temporary distraction, or by overreliance on automatic go-responding, or by a motor output error), and as such are conceptualized as additional noise in the MRI-signal corresponding to commission errors.

Sustained attention to response task (SART)

Participants performed the random SART, in which numbers from 1-9 are presented in a random (i.e. non-sequential) order. In each trial (see Figure 1) a single digit appeared on the screen for 313 ms; a mask was then presented for 125 ms, after which a response cue (a boldened cross) appeared for 63 ms, followed by a second mask for 375ms and a fixation cross for 563 ms. The total inter-stimulus interval was 1439 ms (digit onset to digit onset). Participants were instructed to respond, using a button press, to every digit (Go-trial) except '3' (No-Go trial). They were asked to respond when the response cue appeared on screen 125 ms after the digit was extinguished, or 438 ms from the start of the trial. The response cue was used to limit unwanted performance differences in response variability. The task was presented using E-prime (Psychology Software Tools, Pittsburgh, USA), in a single block of 450 trials (of which 50 were No-Go-trials), which included two 30s breaks after 150 and 300 trials. The total duration of the task was approximately 12min.

Figure 1

MRI data acquisition

All scanning was conducted on a Philips Intera Achieva 3.0 Tesla MR system. Each scanning sequence began with a reference scan to resolve sensitivity variations. A parallel Sensitivity Encoding (SENSE) approach (Pruessmann et al., 1999) with a reduction factor of 2 was utilised for all T1-weighted image acquisitions. 180 high-resolution T1-weighted anatomic MPRAGE axial images (FOV 230 mm, thickness 0.9 mm, voxel size $0.9 \times 0.9 \times 0.9$) were then acquired (total duration 325 s), to allow subsequent activation localization and spatial normalization.

Functional data were collected using a T2-weighted echo-planar imaging (EPI) sequence that acquired 32 non-contiguous (10% gap) 3.5 mm axial slices covering the

1
2
3 entire brain (TE = 35 ms, TR = 2000 ms, FOV 224 mm, 64 × 64 mm matrix size in
4 Fourier space). The functional scans had a total duration of 730 s.
5
6

7 8 **fMRI analysis** 9

10
11 The data were analysed using AFNI (Cox, 1996; <http://afni.nimh.gov>). Images
12 were corrected for motion (using a least-squares alignment allowing translations and
13 rotations), and activation outside the brain was removed. Separate impulse response
14 functions (IRFs) were estimated² for successful inhibitions and commission errors using
15 deconvolution techniques. Gamma-variate functions were fit, voxelwise, to these IRFs
16 using a non-linear regression programme. A percentage signal-change score (%SC) was
17 calculated by dividing the area under the curve of these functions by the area under the
18 baseline which, in this case, reflects tonic ongoing processes involved in Go trial
19 responses. Individual %SC maps were then spatially blurred using a 3mm rms isotropic
20 Gaussian kernel, and transformed into MNI space using the MNI (Montréal Neurological
21 Institute) 152-brain template.
22
23
24
25
26
27
28
29
30

31 For both commission errors and successful inhibitions, group activation maps
32 were then determined using one-sample t-tests against 0 (i.e. against the null hypothesis
33 of no change in activation compared with the baseline). Significant voxels passed a
34 voxelwise statistical threshold ($t(19)=3.88$, $p \leq .001$), and were required to be part of a
35 cluster of significant voxels with a minimum volume of 141 μl . This minimum cluster-
36 size was determined using Monte-Carlo simulations, with a probability of .05 (corrected)
37 of a cluster surviving due to chance. Separate maps were generated for the adults and
38 young adolescents, and these were subsequently combined into a single map which
39 contained every voxel that survived thresholding in either of the two groups. These
40 resulting maps (one for successful inhibitions, and one for commission errors) were then
41 used as regions of interest (ROI) to extract mean activation values for each region for
42
43
44
45
46
47
48
49
50
51
52

53 ² Separate IRF functions were calculated for each participant, which reduces the effects of (limited)
54 differences in the shape of the BOLD-signal that may exist between the two groups. For example, it is
55 likely that response inhibition might be faster for adults compared to young adolescents, which might lead
56 to a shorter interval between the stimulus and the onset of the BOLD signal. With the present method, any
57 such differences in e.g. the onset of the BOLD signal are unlikely to affect the activation maps.
58
59
60
61
62
63
64
65

1
2
3 every participant. These data were used for independent group t-tests. The subsample of
4 performance-matched participants was investigated using these same ROIs.
5

6
7 In addition to this, we also performed a direct voxelwise comparison between the
8 two groups (using the same ROIs that were identified for successful inhibitions and for
9 commission errors), to rule out a potential confound between activation amplitude and
10 activation extent. Within these regions, significant voxels passed a voxelwise statistical
11 threshold ($t(38)=3.57$, $p \leq .001$). Minimum cluster size (to control for multiple
12 comparisons, with a probability of .05 of a cluster surviving due to chance) was 73 μ l for
13 successful inhibitions, and 69 μ l for commission errors. The resulting clusters identify
14 subregions of the ROIs that differ only in activation amplitude, between the adults and
15 the young adolescents.

18
19
20
21
22
23

24 **Analysis of behavioural data**

25
26
27 Errors of commission (responses made on the No-Go digit 3, which indicate
28 failure of inhibitory processes) and omission (non-responses on the Go-trials, believed to
29 reflect temporary lapses in attention) were calculated for each participant. Independent
30 groups t-tests were used to investigate differences between the two groups with the alpha
31 level set at .05. Variability of response times has been previously suggested as an index
32 of top-down executive control (West et al., 2002), and ICV scores have been previously
33 associated with inhibitory success as well as frontal, parietal and thalamic activation
34 during response inhibition (Bellgrove, Hester, & Garavan, 2004). We therefore also
35 compared the mean and Intra-individual Coefficient of Variability (ICV) (SD Go-
36 RT/ $mean$ Go-RT, see Stuss et al., 2003) of the response times (RTs) on the Go-trials
37 between the groups.

RESULTS

Behavioural performance

Adults made significantly fewer errors of omission ($t(38)=2.25$, $p=.03$) and significantly fewer errors of commission ($t(38)=3.74$, $p=.001$) compared with young adolescents (see Figure 2). There was no significant difference in RTs between the adults and young adolescents on Go trials ($t(38)=.81$, $p=.42$) or on commission errors ($t(38)=0.75$, $p=.46$). Both adults and young adolescents had faster RTs when making commission errors compared with RTs on Go-trials ($t(19)=7.08$, $p<.001$; and $t(19)=5.88$, $p<.001$, respectively). Young adolescents showed higher ICVs on Go-trials compared to adults ($t(38)=2.84$, $p=.007$). Response variability correlated with the number of omission errors for young adolescents ($r=.66$, $p=.002$) but not for adults ($r=.36$, $p=.119$), and correlated with the number of commission errors for both young adolescents ($r=.79$, $p<.001$) and adults ($r=.53$, $p=.016$).

Figure 2

fMRI analysis: successful inhibitions

Table 1

1
2
3 Table 1 lists the areas that showed significant activity when participants
4 successfully inhibited their response on No-Go trials. Seventeen³ of these 23 regions
5 showed significant differences between the two groups, with young adolescents
6 demonstrating higher activation in the right ($p=.016$) and left ($p=.023$) middle frontal
7 gyri, right ($p<.001$) and left ($p<.001$) inferior frontal gyri, left posterior superior frontal
8 gyrus ($p<.001$), right ($p=.01$) and left ($p=.007$) inferior parietal cortex, right ($p=.007$) and
9 left ($p=.026$) cuneii, right middle temporal gyrus ($p=.026$), bilateral anterior ($p<.001$) and
10 posterior ($p=.003$) cingulates, right ($p=.011$) and left ($p=.002$) insulae, left lentiform
11 nucleus ($p=.001$) and left caudate ($p=.018$). Adults showed a significantly larger increase
12 in only one region, the anterior part of the left superior frontal gyrus ($p=.001$; See Figure
13 3).

Nine of these regions contained clusters that showed significant voxelwise differences in activation amplitude, between the adults and the young adolescents: young adolescents demonstrated higher activation amplitude in the left middle frontal gyrus, right inferior frontal gyrus, right inferior parietal cortex, right cuneus, right middle temporal gyrus, bilateral ACC and PCC, and left insula; adults showed higher activation amplitude in the anterior part of the left superior frontal gyrus (all $p<.001$). In the remaining eight regions which showed activation differences for the region but no significant clusters of voxelwise differences, group effects may be driven by differences in activation extent (i.e. the young adolescents activating more voxels in the ROI, but with a similar amplitude as was observed for adults). It should however be noted that this is a tentative conclusion given that activation and amplitude and activation extent become confounded when one spatially blurs data to enable group averages and group comparisons.

The adults showed a significant correlation between ICV-scores and activation in the medial region of the left superior frontal gyrus ($r=.47$, $p=.035$), while in young adolescents ICV-scores correlated positively with activation in the left lentiform nucleus

³ If male participants only are compared (to avoid gender-bias), activation differences in the right insula ($t(33)=2$, $p=.053$), right middle frontal gyrus ($t(33)=1.68$, $p=.103$), left middle frontal gyrus ($t(33)=1.88$, $p=.069$), right middle temporal gyrus ($t(33)=1.75$, $p=.09$), and left caudate ($t(33)=1.5$, $p=.14$) are no longer significant. All remaining differences remain significant.

26 Table 2

27 ---
28
29
30

31 Table 2 lists the areas of significant activation when participants made
32 commissions errors (also see Figure 4). Of these 22 regions, nine⁴ showed a significant
33 difference between the adults and the young adolescents, with adults showing higher
34 activation than young adolescents for all. This pattern was observed in the bilateral
35 cerebellar culmen (p<.001), right parahippocampal gyrus (p=.006), the right lingual gyrus
36 and two regions in the left lingual gyrus (all p<.001), the left insula (p=.016), the right
37 claustrum (p<.001), and also in the right caudate (p=.016) and fusiform gyrus (p=.002).
38
39
40
41
42
43

44 Of these regions, six contained clusters of voxels that showed a significant
45 difference in activation amplitude: the right and left insulae, bilateral culmen, right
46 claustrum, left lingual gyrus, as well as the right fusiform gyrus (all p<.001). In all these
47 regions, activation amplitude was higher for the adults, compared to the young
48 adolescents.
49
50
51
52
53
54
55

56 ⁴ If we only compare the male participants (to avoid gender-bias), the activation difference in the right
57 parahippocampal gyrus is no longer significant (t(33)=2.02, p=.052). All other effects remain significant.
58
59
60
61
62
63
64
65

1
2
3 Young adolescents showed significant negative correlations between response
4 variability (ICV-scores) and %SC with a number of regions, including right ($r=-.46$,
5 $p=.039$) and left ($r=-.46$, $p=.042$) insulae, right ($r=-.46$, $p=.039$) and left ($r=-.48$, $p=.031$)
6 parietal cortices, right superior frontal gyrus ($r=-.47$, $p=.036$), and right precuneus ($r=-$
7 $.46$, $p=.042$). A positive correlation was observed in the right claustrum ($r=.45$, $p=.048$).
8 There were no significant correlations between ICV-scores and activation measures for
9 the adults.

Performance-matched subsample

Behavioural performance

29
30
31
32
33
34
35 The subsample was selected by excluding the adults whose number of
36 commission errors was lower than one S.E.M. below the mean number of errors, and a
37 corresponding number of young adolescents who made the most commission errors. In
38 the subsample, there were no significant differences between the young adolescents and
39 adults on any of the performance variables, except young adolescents showed slower RTs
40 when making errors on the No-Go-trials ($t(22)=2.7$, $p<.001$) and a trend for slower RTs
41 on Go-trials ($t(22)=1.8$, $p=.086$) (all other t -values $\leq .14$) (See Figure 5). We observed no
42 significant correlations between performance-measures in either the young adolescents or
43 the adults of the subsample.
44
45
46
47
48
49
50

Figure 5

fMRI-analysis & functional correlations: successful inhibitions

In the subsample matched for performance, young adolescents had significantly greater activation compared to adults in eleven regions: right ($p=.005$) and left ($p=.007$) inferior frontal gyri, posterior left superior frontal gyrus ($p=.005$), left inferior parietal cortex ($p=.028$), right ($p=.015$) and left ($p=.025$) cunei, right ($p=.022$), and left ($p=.043$) insulae, left lentiform nucleus ($p=.004$), as well as in the ACC ($p=.015$) and PCC ($p=.045$). Activation in the anterior part of the left superior frontal gyrus, the left and right middle superior gyri, the right inferior parietal cortex, and the right middle temporal gyrus no longer differed reliably.

ICV scores correlated with activation during successful inhibitions in the (anterior part of the) left superior frontal gyrus ($r=.69$, $p=.013$) for adults, though there were no longer reliable correlations with activation scores for the young adolescents.

fMRI-analysis & functional correlations: commission errors

In the sample matched for performance, adults showed a greater increase in activation in bilateral culmen ($p=.006$), two regions on the left lingual gyrus ($p<.001$ and $p=.011$), and the right claustrum ($p=.008$). There were no longer significant differences in the left insula, right caudate, right parahippocampal gyrus, right fusiform gyrus, or the right lingual gyrus.

Young adolescents showed negative correlations between ICV-scores and activation changes in the left middle ($r=-.61$, $p=.036$) and superior ($r=-.62$, $p=.033$) frontal gyri, while no significant correlations with ICV scores were seen in the adults

DISCUSSION

The present study confirms previous behavioural studies that found better response inhibition (fewer commission errors) and sustained attention performance (fewer errors of omission and lower response variability) in adults compared to adolescents/children (Daniel, Pelotte, & Lewis, 2000; Luna, Garver, Urban, Lazar, &

1
2
3 Sweeney, 2004) (Clark et al., 2006; Lin, Hsiao & Chen, 1999; though also see Karatekin,
4 Marcus & Couperus, 2007). Greater response variability has been previously identified in
5 clinical groups with frontal (Stuss et al., 2003) and fronto-striatal and fronto-parietal
6 brain pathology (e.g. ADHD, see Castellanos et al., 2005; Johnson et al., 2007b). In the
7 current sample the greater response variability for young adolescents likely reflects that
8 these frontal regions are not yet fully matured. This is also consistent with the young
9 adolescents showing negative correlations between response variability and activation
10 changes in most regions, suggesting that lower variability is associated with more ‘adult-
11 like’ activations (during commission errors, as well as in the superior frontal gyrus during
12 successful inhibitions).
13
14

15
16
17
18
19
20
21 During successful inhibitions, young adolescents showed increased recruitment,
22 compared with adults, of a widely distributed network, including left (inferior, superior
23 and middle) and right (middle and inferior) frontal gyri, left and right insulae, bilateral
24 anterior and posterior cingulate, as well as both left and right inferior parietal cortex and
25 left and right precunei and cunei. Adults showed higher activation only in the left
26 superior frontal gyrus. The superior behavioural performance and the reduced brain
27 activation levels of adults support the notion that the network underlying response
28 inhibition becomes more sparsely represented as the system matures. To investigate
29 whether this pattern of differences was likely caused by developmental changes to the
30 underlying networks, or simply emerged because of differences in performance, we also
31 compared two groups matched for performance. Although the same overall pattern
32 emerged (with young adolescents showing greater activation in frontal, parietal, and
33 medial regions), there were no longer reliable differences in a number of (predominantly
34 frontal) regions. Thus, although we cannot rule out that performance differences affect
35 the differences in activation maps between the adults and the young adolescents, the
36 young adolescents still rely on a more extensive network during successful inhibitions
37 when performance is equated. There was no indication of a shift in the direction of
38 activation differences (i.e. increased activation for adults compared to young adolescents)
39 when performance was matched between the groups. One limitation to this approach is
40 that our performance matching relied on an arbitrary selection of participants, to ensure
41 equal numbers of (both omission and commission) errors. Our focus on equating for the

2
3 number of error trials (rather than any other variable, such as response times or ICV-
4 scores) aimed to investigate the possibility that inconsistent results from prior studies
5 (with some showing increased activation for children or adolescents compared to adults,
6 and other studies showing the opposite) might have been related to whether or not these
7 studies used matched performance in terms of commission errors. While it would be very
8 informative to investigate the relative effects of differences in error-rates, response
9 latencies and variability, on the activation patterns that underlie response inhibition and
10 error-monitoring, this inquiry exceeds the aims of the present study.

11
12
13
14
15
16
17 This pattern of results is consistent with earlier findings (Booth et al., 2003; Casey
18 et al., 1997; Durston et al., 2002), but opposite to the findings of Rubia and colleagues
19 (2006; 2007), which may be due, in part, to the latter studies using paradigms that also
20 engage response selection and spatial judgement, in addition to response inhibition. This
21 is suggested by a clear dichotomy in the nature of the tasks that were used in prior
22 studies: those that found increased activation for younger, compared to older participants,
23 used go/nogo tasks to probe response inhibition (Booth et al., 2003; Casey et al., 1997;
24 Durston et al., 2002; 2006; this paper; also see Tamm, Menon & Reiss, 2002). On the
25 other hand, those studies that found the opposite pattern, i.e. higher activation for adults,
26 employed tasks that required spatial discrimination (Bunge et al., 2002; Rubia et al.,
27 2006; 2007).

28
29
30
31
32
33
34
35
36
37 In line with longitudinal findings (Durston et al., 2006) showing a progression
38 from diffuse to more focal activation patterns, there was only one region that showed
39 higher activation in the adults (the anterior part of the left superior frontal gyrus in our
40 study). This supports the notion that with development of the frontoparietal network
41 underlying response inhibition, activation in non-critical areas is attenuated in favour of
42 key areas, and may represent emerging cortical specialisation (see Durston et al., 2006;
43 Kelly & Garavan, 2005; Ungerleider, Doyon, & Karni, 2002).

3 cerebellar regions including the right caudate and bilateral culmen. When comparing
4 adults and young adolescents with equal performance, this pattern of activation was still
5 observed in the right claustrum, left lingual gyrus, and bilateral culmen. These results,
6 showing an opposite pattern to the relative hyperactivity of the adolescents for successful
7 inhibitions, argue against a non-specific cognitive or vascular basis for the observed age-
8 related changes. They suggest that the relative immaturity of the young adolescent brain
9 translates to a diminished response for errors and requiring greater levels of activity when
10 successfully inhibiting. Indeed, it is possible that the blunted performance monitoring of
11 the young adolescents, as echoed in their diminished error-related response and
12 heightened response variability, may underlie the greater effort (more diffuse activation)
13 when successfully inhibiting. Cerebellar activation has been previously shown in adults
14 as well as adolescents during inhibitory control in Go/No-Go tasks (e.g. Garavan et al.,
15 2003; Rubia et al., 2007), and this region projects to both motor and prefrontal areas
16 through the thalamus (Kim et al., 1994; Middleton & Strick, 2000). Activation of the
17 insula has been previously observed in adults during failed attempts to inhibit and,
18 indeed, may be a key neuroanatomical substrate subserving error detection (Magno,
19 Foxe, Molholm, Robertson & Garavan, 2006; Ramautar, Slagter, Kok & Ridderinkhof,
20 2006). Parahippocampal activity may reflect similar processes, as this region has been
21 implicated in anxiety and arousal (Gray & McNaughton, 2000; also see Green & Arduini,
22 1954) and memory (e.g. Fernandez et al., 1998; also see Jansma et al., 2004). Thus, adults
23 may be better at inhibiting the prepotent response when an unexpected target appears
24 because when they make an error, they have a stronger arousal-mediated response which
25 may engage additional top-down attentional control processes to prevent or limit
26 subsequent inhibitory failures (Hester, Barre, Murphy, Silk & Mattingley, 2008).

44
45 Unlike prior studies (Rubia et al., 2007; Velanova et al., 2008), we did not
46 observe differences in the ACC between the two groups for unsuccessful inhibitions,
47 though this may be because of differences in the paradigms used, or due to lower power
48 in our design. For example, the lack of a difference in ACC activation might be related to
49 the use of a response cue in the SART-paradigm. Increasing time-pressure has been
50 previously found to impair response inhibition in younger, compared to older children
51 (see Cragg & Nation, 2008). Thus, *reducing* time pressure might facilitate the task for the

1
2
3 young adolescents in our study, while adults might benefit less from the cue if their
4 performance is closer to ceiling. Given evidence that the ACC monitors response conflict
5 (Carter et al., 1998) and/or error likelihood (Brown & Braver, 2005), the presence of the response
6 cue may therefore reduce between-group differences in activation in this structure. Additionally,
7 there is some evidence that differences in ACC activation during nogo trials, between adults and
8 adolescents, may strongly depend on the specific age-groups that are compared. For example,
9 Jonkman, Sniedt and Kemner (2007; also see Jonkman, 2006) compared younger (6-7 years) and
10 older (9-10 years) children to young adults (19-23 years) using a cued go/nogo task. They
11 observed differences in ACC involvement, both in terms of an increased nogo N2 ERP response,
12 as well as a reduced Contingent Negative Variation (CNV) effect related to cueing, but only when
13 comparing the youngest group to both older children and adults, while these measures did not
14 differ between the 9-10-year olds and adults. Similarly, at least one other fMRI-study (Stevens,
15 Kiehl, Pearlson & Calhoun, 2009) failed to find age-related differences (in the age-range 11-37)
16 in an error-related network including the ACC, which the authors suggested might indicate that
17 these regions are already relatively mature in adolescence.

33 CONCLUSIONS

34
35
36 In summary, previous research suggests that progressive maturation of the
37 developing brain, and especially (pre)frontal regions which mature relatively late
38 compared with more posterior brain regions, leads to shifts in the specific neural
39 networks that underlie executive functions, including response inhibition. There is,
40 however, less agreement on the direction of these differences, with different studies either
41 showing increased or decreased activation of these regions, for children/adolescents
42 compared with adults. We propose that a significant underlying factor for these divergent
43 findings may be differences in the specific paradigms used, particularly with regards to
44 whether the task taps into processes related to spatial attention, in addition to response
45 inhibition.
46
47
48
49
50
51
52
53

54 The present study also provides further support for the notion that parallel to
55 increases in executive control capacities, the underlying neural networks show a shift
56
57
58
59
60
61
62
63
64
65

1
2
3 from more diffuse activation patterns in young adolescents, to more focal prefrontal
4 activation in adults, with reduced reliance on other regions. Even when the two groups
5 were matched for performance, young adolescents showed increased activation during
6 successful inhibitions in frontal, parietal and medial regions. This suggests that the
7 reliance of young adolescents on a more diffuse network cannot solely be attributed to
8 differences in performance. Additionally, the present data suggest an important role for
9 the integrated function of cerebellar, striatal and (para)hippocampal regions in
10 modulating executive control under circumstances when inhibition has failed and greater
11 control must be exerted.
