Epitaxial spin-filter tunnel junctions based on the ferromagnetic semiconductor europium monoxide (EuO) are investigated by means of density functional theory. In particular, we focus on the spin transport properties of Cu(100)/EuO(100)/Cu(100) junctions. The dependence of the transmission coefficient and the current-voltage curves on the interface spacing and EuO thickness is explained in terms of the EuO density of states and the complex band structure. Furthermore, we also discuss the relation between the spin transport properties and the Cu-EuO interface geometry. The level alignment of the junction is sensitively affected by the interface spacing, since this determines the charge transfer between EuO and the Cu electrodes. Our calculations indicate that EuO epitaxially grown on Cu can act as a perfect spin filter, with a spin polarization of the current close to 100%, and with both the Eu-5d conduction-band and the Eu-4f valence-band states contributing to the coherent transport. For epitaxial EuO on Cu, a symmetry filtering is observed, with the Δ1 states dominating the transmission. This leads to a transport gap larger than the fundamental EuO band gap. Importantly, the high spin polarization of the current is preserved up to large bias voltages.

I. INTRODUCTION

Magnetic tunnel junctions using MgO as a tunnel barrier generally display large tunneling magnetoresistance (TMR) and are now widely used in read heads for ultra-high-density hard disk drives as well as in random access memory devices. Currently, a room-temperature TMR ratio as high as 500% can be reached in junctions made of polycrystalline Fe (more precisely, CoFeB) sandwiching a thin MgO insulating layer. Despite such huge TMR ratios, the Fe/MgO system presents at most a moderate spin polarization of the conduction electrons. As a consequence of this, the energy barrier has a different height for majority and minority spins, which leads to the suppression of the current for one of the two spin species for thick-enough junctions. The tunnel current density is proportional to the energy-dependent transmission coefficient through the barrier, \( T(E) \), which itself depends exponentially on the barrier height \( \Phi \) and the barrier thickness \( t \). This can be written as \( T(E) \propto \exp[-2\kappa(\Phi,E)] \), where \( \kappa(\Phi,E) = \sqrt{2m_e(\Phi - E)}/h \), and with \( m_e \) being the electron mass. Clearly, if the barrier height is different for the different spin species, then the current polarizations will increase exponentially with the insulating layer thickness, leading to full spin polarization for thick barriers. Devices constructed with this principle are called spin-filter tunnel junctions (SFTJs). The quest for manufacturing SFTJs then reduces to that of finding suitable ferromagnetic semiconductors.

The europium chalcogenides EuS, EuSe, and EuO all have a rocksalt structure and are all ferromagnetic insulators. Among these, EuO presents the largest conduction-band (\( E_{\text{CB}} \)) and the largest spin polarization of the current, \( \approx 65\% \) (for CoFeB). We note that the Julliere model, which predicts a much smaller TMR, fails in the present context.

Another possible strategy for obtaining a spin-filter effect, and thus very large TMR ratios, is that of using a ferromagnetic insulator as a spacer between the metallic electrodes. In this case, the energy barrier has a different height for majority and minority spins, which leads to the suppression of the current for one of the two spin species for thick-enough junctions. The tunnel current density is proportional to the energy-dependent transmission coefficient through the barrier, \( T(E) \), which itself depends exponentially on the barrier height \( \Phi \) and the barrier thickness \( t \). This can be written as \( T(E) \propto \exp[-2\kappa(\Phi,E)] \), where \( \kappa(\Phi,E) = \sqrt{2m_e(\Phi - E)}/h \), and with \( m_e \) being the electron mass. Clearly, if the barrier height is different for the different spin species, then the current polarizations will increase exponentially with the insulating layer thickness, leading to full spin polarization for thick barriers. Devices constructed with this principle are called spin-filter tunnel junctions (SFTJs). The quest for manufacturing SFTJs then reduces to that of finding suitable ferromagnetic semiconductors.

The europium chalcogenides EuS, EuSe, and EuO all have a rocksalt structure and are all ferromagnetic insulators. Among these, EuO presents the largest conduction-band exchange splitting, \( \approx 0.54 \, \text{eV} \), below the material’s Curie temperature of 69 K. In EuO, the divalent Eu ions possess a large local moment originating from the half-filled 4f band (\( \mu_{\text{Eu}} \approx 7 \mu_B \)). An energy gap of 1.0 eV separates the half-filled majority Eu-4f band from the Eu-5d conduction band. SFTJs based on polycrystalline EuO in the form of a metal/EuO/metal heterojunction have been studied in several recent experiments. However, the spin transport properties of crystalline epitaxial EuO junctions have not been studied theoretically so far. The purpose of this paper is to provide such theoretical insight. In particular, we present \( \textit{ab initio} \) results for the electronic structure and the electron transmission through...
EuO barriers sandwiched between Cu electrodes oriented along the [001] direction.

Our paper is organized as follows. We start our discussion by presenting the methods used and the structure of the device investigated. Then, in the following Sec. III, we present the electronic structure of EuO and its complex band structure along the [001] direction. This determines the spin-dependent decay rates and thus the spin-filter efficiency. In Sec. IV, we discuss the transmission coefficient at zero bias, while in Sec. V, the dependence of the spin transport on the EuO thickness is analyzed and related to the complex band structure. The current-voltage (I-V) characteristics are discussed in the following section, where we find that in contrast to Fe/MgO junctions, the polarization of the current is not reduced by the applied bias. Finally, we conclude.

II. METHODS

The EuO and Cu electronic structures are calculated using the ab initio density functional theory (DFT) code SIESTA. Since the local density approximation (LDA) is not sufficient to give an accurate description of the EuO density of states (DOS), we correct for on-site Coulomb repulsion with an LDA+U treatment. Following Ref. 26, the exchange constant J and the on-site orbital potential U for the Eu-4f orbitals are set, respectively, to \( J_f = 0.77 \) eV and \( U_f = 8.3 \) eV, while for the O-2p orbitals, we use \( J_p = 1.2 \) eV and \( U_p = 4.6 \) eV. Troullier-Martins norm-converging relativistic pseudopotentials are used for Cu, Eu, and O. The wave functions are expanded over a double-\( \zeta \) plus polarization (DZP) basis set, except for the Eu-4f states for which we use single \( \zeta \). An equivalent real-space mesh cutoff of 600 Ry is used together with an electronic temperature of 69 K. We sample the Brillouin zone (BZ) in the plane perpendicular to the transport direction over a \( 7 \times 7 \) point uniform mesh.

Spin transport is studied by using the SMEAGOL electronic transport code, which combines DFT with the nonequilibrium Green’s function (NEGF) technique. SMEAGOL uses the Hamiltonian matrix provided by SIESTA to calculate the charge density, so that the same pseudopotentials and exchange and correlation function can be used for both the electronic structure and the transport. The spin current at each bias voltage is calculated by energy integration of the spin-dependent transmission coefficient \( T^\sigma \):

\[
I^\sigma = \frac{e}{h} \int dE T^\sigma(E,V) \left[ f \left( E - \frac{eV}{2} \right) - f \left( E + \frac{eV}{2} \right) \right].
\]

where \( \sigma \) is the spin index (\( \sigma = \uparrow, \downarrow \)), \( f \) is the Fermi function, \( V \) is the applied bias voltage, and \( e \) is the electron charge. The total transmission coefficient is obtained by integrating the \( k \)-dependent transmission \( T^\sigma(E,V,k_x,k_y) \) over the two-dimensional BZ perpendicular to the transport direction,

\[
T^\sigma(E,V) = \frac{1}{\Omega} \int dk_x dk_y T^\sigma(E,V,k_x,k_y),
\]

where \( \Omega \) is the area of the BZ. We denote \( T(E) = T(E,V = 0) \) as the zero-bias transmission coefficient. In our calculations, we assume the lattice structure to be periodic in the \( x \)-\( y \) plane, and we keep the transport direction along the \( z \) axis.

While \( 7 \times 7 \) \( k \) points are enough to accurately converge the charge density, the presence of resonances in \( T^\sigma(E,V,k_x,k_y) \) requires the much larger mesh of 100 \( \times \) 100 to evaluate the transmission coefficient both for zero and finite bias. The I-V characteristics are calculated non-self-consistently by evaluating the transmission coefficient over an effective bias-dependent Hamiltonian matrix, which in turn is obtained by adding a rigid shift to the zero-bias Hamiltonian matrix elements of the electrodes and a linear potential across the insulating barrier. This is a good approximation to the self-consistent potential drop for tunnel junctions, which appears essentially like that of a standard parallel-plate capacitor.

EuO crystallizes in the rocksalt structure with a lattice constant of \( a_{EuO} = 5.144 \) Å. The primitive face-centered cubic (fcc) unit cell containing one Eu and one O atom is shown in Fig. 1(a). Since we consider transport along the [001] direction, we have to use, as a basic building block for the EuO spacer, a cell with size and orientation different from that of the primitive one. The smallest possible cell thus has tetragonal symmetry, and contains two Eu and two O atoms [see Fig. 1(b)]. By stacking multiples of such tetragonal cells along the \( z \) direction, we can construct barriers of arbitrary thickness, where one cell contains two EuO monolayers (MLs).

The model spin-filter junction considered here consists of \( n \) MLs of EuO sandwiched between nonmagnetic Cu electrodes, with \( n \) being an integer. As electrode material, we consider fcc Cu oriented along the [001] direction (lattice constant 3.61 Å), which is a material choice that has been adopted in several experiments. When the tetragonal EuO unit cell is used, the lattice constant of Cu can be matched with only a slight strain to the EuO lattice, since the dimensions along \( x \) and \( y \) are \( a_{EuO}/\sqrt{2} = 3.63 \) Å. The junction setup is illustrated in Fig. 2. In this basic setup, both the O and Eu atoms are placed over the...
hollow sites of the Cu surface. We also perform calculations for EuO shifted in the x-y plane. However, the transport and spin-filter properties are not sensitively dependent on such a shift. The equilibrium interface distance along the z direction, \(d\), between Cu and EuO is found to be \(d = 2.8\ \text{Å}\). This value is plausible when comparing with the interface between Au and MgO, which is found to be \(2.5\ \text{Å}\).\(^\text{30,31}\) Note that we do not consider possible oxidation at the Cu/EuO interface, or the formation of secondary EuO phases.

III. EuO ELECTRONIC STRUCTURE

Let us start our discussion by describing the electronic structure of EuO. The calculated EuO band structures for both the primitive fcc and the tetragonal unit cells are presented, respectively, in Figs. 3 and 5. The results agree rather well with previously published calculations.\(^\text{26,32}\) In order to compare the band structures for two cells, we use the same \(k\)-space path. Standard high-symmetry points are specified for the primitive fcc BZ and also for the primitive tetragonal BZ (where applicable). We note that due to band folding for the tetragonal cell, we find twice the number of bands than for the primitive fcc one. The \(X\) point [located at \((\pi/2\text{EuO},0,0)\)] and the \(X'\) point [located at \((0,0,\pi/2\text{EuO})\)] are equivalent in the fcc BZ. However, for the tetragonal cell, they are independent since the \(X'\) point is equivalent to \(\Gamma\) in the tetragonal cell. There is a band gap of about 1.0 eV for majority spins (Fig. 3), whereas the gap increases to about 3.5 eV for the minority spins. For the primitive fcc cell (Fig. 3), we find an indirect gap, where the top of the valence band is at \(\Gamma\) and the bottom of the conduction band is at the \(X'\) point. This gap becomes direct when the primitive tetragonal cell is used due to band folding (Fig. 5). Note that the tetragonal cell is the relevant one for the transport, so that EuO along the [001] direction behaves as a direct-gap ferromagnetic semiconductor.

We first consider the electronic band structure of the majority spins, for which the energy spectrum consists of three parts: the conduction bands, the top valence bands, and the lower valence bands. The top valence bands are found in the range between \(-1.6\) and \(-0.5\) eV (we set the zero energy approximately at the middle of the gap). It is clearly seen from Fig. 4, where we show the projected DOS (PDOS) on different orbitals, that the main character of the top valence band is given by the Eu-4\(f\) states. While many of the Eu-4\(f\) bands show very little dispersion, indicating strong localization, in

![FIG. 4.](image)

**FIG. 4.** (Color online) EuO density of states projected over the following atomic orbitals: O-2\(p\), Eu-6\(s\), Eu-5\(d\), and Eu-4\(f\).

EuO the Eu-4\(f\)/O-2\(p\) mixing leads to a significant dispersion around the \(\Gamma\) point. This is an indication of delocalized states. We note that at the top of the valence band, Eu-4\(f\) and O-2\(p\) contribute approximately equally to the density of states. In addition, the hybridization leads to a large contribution to the intersite coupling of kinetic processes.\(^\text{33}\) We therefore expect such delocalized states to contribute significantly to the transport through a EuO barrier. Below the top valence bands, the bottom valence bands are observed in the energy range from \(-4.9\) to \(-3.0\) eV. It is seen from Fig. 4 that the bottom valence bands are dominated by O-2\(p\) states. The bandwidth of the O-2\(p\) states (1.9 eV) is not much larger than that of the Eu-4\(f\) states (1.0 eV), which indicates a similar wave-function delocalization. The energy gap between the top valence and bottom conduction bands is about 1.0 eV. The

![FIG. 5.](image)

**FIG. 5.** (Color online) LDA+\(U\) band structure of EuO for the primitive tetragonal unit cell [see Fig. 1(b)], with majority-spin bands in the left panel and minority-spin bands in the right panel. Due to the doubled size unit cell, compared to the primitive fcc one, a band down-folding makes the \(\Gamma\) point and the fcc \(X'\) point equivalent. This leads to a direct gap at \(\Gamma\).
lower conduction bands are dominated by Eu-5d states. Above 1.6 eV, we find also contributions from the Eu-6s orbitals. We note that the DOS at the lower end of the conduction bands is very small, which is due to a high dispersion.

Next we consider the electronic band structure of the minority spins. The empty Eu-4f states start at around 11.1 eV, so that they are not expected to affect the transport properties. As for the majority states, the conduction bands are dominated by Eu-5d and Eu-6s orbitals, while the valence bands are dominated by O-2p. The spin-filter character of EuO is due to a spin splitting of the bands, which leads to a difference in the band gaps for the majority and minority spins. The splitting between the majority- and minority-spin conduction bands is calculated to be about 0.6 eV, in agreement with previous theoretical studies and with recent experiments using three-dimensional (3D) angle-resolved photoemission spectroscopy. The Eu-6s states show a spin splitting similar to the Eu-5d states, namely, 0.4 eV.

We now analyze the symmetries of the different bands. Symmetries are important for the transport through epitaxial tunnel junctions, since at any given energy, only evanescent states in the insulating barrier with matching symmetry with propagating Bloch states in the electrodes can contribute to the conductance. Since the EuO gap in the tetragonal cell is at \( \Gamma \), the transport will be dominated by states close to \( k_z = k_y = 0 \), denoted as \( \Gamma_{2D} \), for which the barrier height is smallest (the coordinate system is defined in Fig. 1). In the energy range comprised between \(-1.8 \) and \( 1.6 \) eV around \( E_F \), the Cu electrodes have only states of \( \Delta_1 \) symmetry with respect to the \( z \) axis. For a cubic space group, the \( \Delta_1 \) symmetry transforms as a linear combination of \( x (p_z \text{ orbitals}), z (p_z \text{ orbitals}), 2z^2 - x^2 - y^2 (d_z \text{ orbitals}), \) and \( z(2z^2 - 3x^2 - 3y^2) (f_z \text{ orbitals}) \). Above 1.6 eV, the Cu states have \( \Delta_5 \) symmetry. The \( \Delta_5 \) symmetry transforms as a linear combination of \( x (p_z \text{ orbitals}), y (p_z \text{ orbitals}), xz (d_z \text{ orbitals}), \) and \( yz (d_z \text{ orbitals}) \). At energies below \(-1.8 \) eV, we find the Cu-3d orbitals, so that there are also states with different symmetries. For a transport measurement up to about 2 V, we therefore expect the states with \( \Delta_1 \) symmetry to determine the transport properties.

In order to investigate in more detail the propagating and evanescent states in the EuO barrier, we calculate the complex band structure (Fig. 6) at \( \Gamma_{2D} \) (Refs. 4, 39, and 40) and analyze the symmetries of the evanescent states. Real wave vectors \((\text{Im}[k_z] = 0)\) represent propagating states and complex wave vectors; \(\text{Im}[k_z] \neq 0\) represent evanescent states since their wave functions decay as \(\exp(-\text{Im}[k_z] \cdot z)\) across the barrier. For the majority spins, the top of the valence band is threefold degenerate, with one state with \( \Delta_1 \) symmetry (Eu-4f\(_z\), and O-2p\(_z\) orbitals) and two states with \( \Delta_5 \) symmetry. Since the state with \( \Delta_1 \) symmetry has a lower effective mass than those with \( \Delta_5 \) symmetry, the corresponding \( \Delta_1 \) evanescent states have smaller \( \text{Im}[k_z] \), and therefore a slower decay. The bottom of the conduction band is given by a state with \( \Delta_2 \) symmetry (Eu-5d\(_{x^2-y^2}\) orbital). At 1.6 eV, we find the Eu-4s states, which have \( \Delta_1 \) symmetry. Therefore \( \text{Im}[k_z] \) for the \( \Delta_1 \) band forms a semicircle between the Eu-4f\(_z\) states at the top of the valence band and the Eu-4s states at 1.6 eV.

Consequently, we expect the tunneling transmission to be dominated by the \( \Delta_1 \) states in this energy range. The Eu-5d propagating states with \( \Delta_2 \) symmetry cannot couple to the \( \Delta_1 \) Cu states, and therefore are not expected to contribute significantly to the transmission. For \( k_z \) and \( k_y \) different from zero, the Eu-5d states are no longer fully orthogonal to the Cu-4s states. However, since the gap increases with increasing \( k_z \) and \( k_y \), the barrier height for such states is larger. Hence their contributions to the total transmission are smaller. Overall, one expects a rather weak coupling to the Cu-4s states and a low transmission for states at the bottom of the EuO conduction band.

In the minority-spins bands, there are also three degenerate states at the top of the valence band: one with \( \Delta_1 \) symmetry (O-2p\(_z\) orbital) and two with \( \Delta_5 \) symmetry (O-2p\(_x\) and O-2p\(_y\) orbitals). The \( \Delta_1 \) state again has lower effective mass and therefore a smaller decay for evanescent states. At the bottom of the conduction band, the symmetries are analogous to those of the majority spins. We therefore also expect the minority conductance to be dominated by the \( \Delta_1 \) symmetry. However, since the minority band gap is much larger than that of the majority spins, \( \text{Im}[k_z] \) is also significantly larger for \( \Delta_1 \) states in the gap. As a consequence, we expect \( T^\uparrow \) to be substantially larger than \( T^\downarrow \). This is usually attributed only to different energies of the bottom of the conduction band, whereas our complex band structure analysis indicates that the decay of the evanescent states has significant contributions also from states in the valence band, especially for the majority spins. We note that the Eu-5d \( \Delta_2 \) states will contribute to the transport if different electrodes, possessing \( \Delta_2 \) symmetry states in the relevant energy range, are used.

IV. SPIN TRANSPORT PROPERTIES OF THE EUO JUNCTION AT ZERO BIAS

In this section, we analyze the zero-bias transport properties of Cu/EuO/Cu junctions by taking as an example a stack containing nine MLs of EuO (\( t = 20.58 \) Å). The energy-level alignment between the metal and the insulator is an important factor determining the transport properties of the junction.
the interface between Cu and EuO is not well defined. In actual junctions usually contain polycrystalline EuO, so that comprising nine MLs EuO. The PDOS is calculated at (a) the center comparing the work functions, $W$, Hartree electrostatic potential, the work functions of EuO and Cu are calculated by using the

$$V_{\text{EuO}} = \frac{1}{2} (E_{\text{EuO}} + E_{\text{Cu}})$$

and the vacuum $V_{\text{vacuum}}$ of a Cu slab, while $V_{\text{EuO}}$ is given by the difference between $V_{\text{vacuum}}$ and the energy of the valence-band top of a EuO slab, $V_{\text{VB}}$. We calculate $W_{\text{Cu}} = 3.9$ eV, which is somewhat lower than the theoretical values, ranging between 4.5 to 5.3 eV, and the experimental value of about 4.65 eV. Although the value of the calculated work function depends sensitively on the used parameters, we find that the transmission coefficient does not change significantly. The value for EuO, i.e., $W_{\text{EuO}} = 1.8$ eV, is in good agreement with the experimental value of 1.7 eV. Since $W_{\text{EuO}} < W_{\text{Cu}}$, electron transfer from EuO to Cu can be expected at the interface, leading to the pinning of the valence-band top of EuO to the Cu $E_F$. This is indeed the case for the equilibrium distance ($d = 2.8$ Å), where the Eu-$4f$ states are located just below $E_F$ [see Figs. 7(c) and 7(d)].

In experiments investigating bias-dependent transport, the actual junctions usually contain polycrystalline EuO, so that the interface between Cu and EuO is not well defined. In our calculations, in contrast, we assume a perfect epitaxial interface and do not explicitly consider the formation of defects, oxidation of Cu, or the possible formation of Eu$_2$O$_3$ at the interface. The effect of such modifications of the interface on the electronic structure are manifold, with the most important being that they usually lead to a different charge transfer and therefore to a different band alignment between Cu and EuO. In practice, this means that (depending on the detailed structure of the interface, which is determined by the experimental conditions) $E_F$ can be placed at different positions across the EuO gap. In our calculations, we can tune the charge transfer and consequently the position of $E_F$ in the EuO gap by modifying the distance $d$ between Cu and EuO at the interface. We find that by decreasing the distance from the equilibrium one, i.e., increasing the coupling between Cu and EuO, the EuO states shift to lower energies with respect to $E_F$. For $d = 2.4$ Å, $E_F$ is located approximately in the middle of the gap [see Figs. 7(a) and 7(b)], while for $d = 2.2$ Å, it is pinned at the EuO conduction-band minimum (not shown). Therefore, $d = 2.2$ Å can be used to simulate the transport properties of n-type EuO, as obtained for O-deficient barriers. In the remainder of this paper, we will present the transport properties for both $d = 2.4$ Å and $d = 2.8$ Å, in order to illustrate the effect of a shift of $E_F$ induced by interface modifications. Importantly, we will demonstrate that for any position of $E_F$, EuO always shows excellent spin-filter characteristics up to high bias voltages. We note that if experimentally a perfect epitaxial junction can be realized, then the measurements should correspond to our results for the equilibrium distance $d = 2.8$ Å.

In Fig. 7, we compare the PDOS of atoms at the Cu/EuO interface with the PDOS of atoms at a maximal distance from the interface (to be considered bulklike). While the two PDOSs are similar for most atomic orbitals, there is a significant difference for the O-2$p$ states. At the interface, the O-2$p$ states extend over a larger energy range as compared to bulklike atoms, indicating a coupling to the Cu substrate. In fact, for $d = 2.4$ Å, the broadening is more pronounced than for $d = 2.8$ Å, which is due to the larger coupling. The PDOS in the middle of the EuO layer is very similar to that of bulk EuO, indicating that in the middle of the junction, one recovers the bulk electronic structure of EuO. Although in Fig. 7 only the fully occupied Cu-$3d$ states are shown, we note that the Cu-$4s$ states determine the transport properties of the electrodes since they have an approximately constant PDOS in a large energy range around $E_F$. In Fig. 7, the Cu-$4s$ PDOS is not shown, since it is not visible on the chosen scale.

The zero-bias transmission coefficient $T(E)$ for different $d$ is shown in Fig. 8 [on a linear scale in Fig. 8(a) and on a logarithmic scale in Fig. 8(b)]. Due to the shift of the electronic states for different $d$ (see Fig. 7), $T(E)$ is shifted towards higher energies for $d = 2.8$ Å as compared to $d = 2.4$ Å, while there is only a minor change in the height of the different transmission peaks. It can be seen that $T(E)$ has two small gaps for the majority spins and one large gap for the the minority ones. For the majority spins, the conduction occurs only through the O-2$p$ states for energies below $-2.5$ eV and through the Eu-5$d$ and Eu-6$s$ states for energies above about 2 eV. For the majority spins, conduction occurs through the same states, and that there is an additional high-transmission region between about $-1.5$ and $-0.5$ eV, which is due to transport through the Eu-$4f$ states. We note that at the bottom Eu-$4f$ band edge at about $-1.5$ eV, the transmission drops sharply by ten orders of magnitude, while at the upper band edge at around $-0.5$ eV, the decrease is less pronounced and more gradual. This is consistent with the results from the complex band structure, which shows a sharp increase of the exponential decay $\text{Im}[\varepsilon_i(x)]$ below the bottom band edge and a gradual increase above the upper band edge. It reflects the high localization of the Eu-$4f$ states at the bottom band edge, in contrast to the top of the valence bands where the Eu-$4f$ states...
FIG. 8. (Color online) Transmission coefficient of a Cu/EuO/Cu junction formed by nine EuO MLs for \(d = 2.4 \, \text{Å}\) and \(d = 2.8 \, \text{Å}\), plotted on a (a) linear and a (b) logarithmic scale. Note that for \(d = 2.8 \, \text{Å}\), \(T(E)\) shifts to higher energy when compared to the case of \(d = 2.4 \, \text{Å}\).

An interlayer distance of \(d = 2.8 \, \text{Å}\) minimizes the energy for the hollow site and is used also for the other configurations to ensure comparability of the transport results. In Fig. 9, we show \(T(E)\) calculated for the different sites, for both \(d = 2.4 \, \text{Å}\) and \(d = 2.8 \, \text{Å}\). Overall, the changes in transmission corresponding to the different sites are rather small, a fact which indicates that the geometry of the Cu/EuO surface does not significantly affect the band alignment and transport properties of the junction.

At the bottom of the conduction band, there are some quantitative differences in transmission between the different sites. This is due to the fact that shifting the O atom with respect to Cu alters the coupling between the Cu-4s and Eu-5d states. As discussed in Sec. III, while the states on the top of the valence band couple well to the \(\Delta_1\) Cu band, the states at the bottom of the conduction band couple only slightly to these states due to a symmetry mismatch. This is also the reason for the fact that the transmission gap is somewhat larger than the EuO band gap, and for the slow increase of the transmission at the bottom of the conduction band with energy. For the bridge and low-symmetry sites, the symmetry mismatch is slightly reduced, resulting in a somewhat smaller transmission gap. Since the results for the different sites are very similar, we will only consider the hollow site in the remainder of the paper.

V. THICKNESS DEPENDENCE OF THE CONDUCTANCE

In this section, we analyze the effect of the EuO thickness \(t\) on the spin transport properties of the Cu/EuO/Cu junction. The transmission spectra for different EuO thicknesses, and for both \(d = 2.4 \, \text{Å}\) and \(d = 2.8 \, \text{Å}\), are shown in Fig. 10. From the figure, it can be seen that the band alignment is not affected by the thickness, while the transmission in the gap decreases exponentially with it. Since for energies in the gap we have \(T^\sigma(E) \propto \exp[-2k^\sigma(E)t]\), we can estimate \(k^\sigma\) from the change...
At thicknesses at coefficient calculated for nine and 11 EuO MLs. The solid lines (T for all thicknesses range between 0 to 1.0 eV, while for the minority ones it extends from −2.5 to 1.6 eV. At d = 2.8 Å, the tunneling gaps of the majority and minority spins for all thicknesses range between −0.1 to 1.75 eV and −2.3 to 2.5 eV, respectively.

The exchange splitting for the conduction band of 0.6 eV matches the value for bulk EuO. The exchange splitting for the conduction band of 0.6 eV matches the value for bulk EuO.

VI. THE I-V CURVE OF THE EUO SPIN FILTER

The spin-resolved current-voltage I-V characteristic and the spin polarization as functions of the bias voltage are shown in Fig. 13 for seven, nine, and 11 MLs of EuO, and for both d = 2.4 and 2.8 Å. The majority-spin current is higher than the minority-spin current for all bias voltages and for all
thicknesses, leading to large polarization in all cases. At low bias, there is a rapid increase of the tunneling current with the bias. This is typical for such systems due to the fact that the current is not only determined by electrons at $E_F$ but also by those in the energy range $E_F \pm eV/2$ (bias window), for which the barrier height can be reduced up to about $eV/2$. At a bias of about 0.7 V for $d = 2.4$ Å, the electrons start to flow through the valence-band top, so that there is a sharp increase in current. The $I$-$V$ curve for $d = 2.4$ Å is in good agreement with experimental results, showing a current onset at a bias of about 1 V, and an increase in current at larger bias. Since for $d = 2.8$ Å the valence band is very close to $E_F$, the onset is found at very low bias. The current increases up to about 1.3 V, above which a decrease with increasing bias is found. This is caused by a reduction of the transmission over the entire bias window once the bias is very large. Such a current reduction results from the enhanced scattering as the potential is tilted inside the barrier due to the applied bias voltage. In these large scattering conditions, incoherent contributions to the current (not included here) are expected to play an important role.

For the minority spins, in contrast, the current remains in the tunneling regime for all bias voltages due to the large barrier height. The large difference between majority- and minority-spin currents is reflected by a high spin polarization $P$ defined as $(I^\uparrow - I^\downarrow)/(I^\uparrow + I^\downarrow)$ [see Fig. 13(c1)]. $P$ remains large for all the bias voltages considered due to the small $I^\downarrow$. We note that the spin splitting of the conduction band (not included here) are expected to play an important role.

The dependences of the $I$-$V$ characteristics and of the differential conductance $G(V) = dI/dV$ on the Cu/EuO interface geometry are addressed in Fig. 14. Overall, the $I$-$V$ characteristics are similar for all the interfaces, which reflects the fact that the zero-bias transmission is also rather similar (see Fig. 9). For $d = 2.4$ Å, there is a sharp increase in $G$ at the current onset, whereas it then stays approximately constant. For $d = 2.8$ Å, in contrast, $G$ is large at low bias and changes sign at 1.3 V.
VII. CONCLUSIONS

We have studied the electronic structure, the complex band structure, and the spin transport properties of epitaxial Cu/EuO/Cu tunnel junctions. The spin transport properties of EuO epitaxially grown on Cu are dominated by the Eu-4f valence states and Eu-5d conduction states. We show that EuO acts as an almost perfect spin filter, where close to 100% spin polarization can be achieved. The polarization increases with increasing EuO thickness as expected from the complex band structure, where the decay of the wave function into EuO is predicted to be much smaller for the majority spins than for the minority ones. Since the conduction states of EuO have no $\Delta_1$ symmetry to match the states in the Cu electrodes, the gap in the transmission coefficient is significantly larger than the band gap of EuO. Under a bias voltage, the spin polarization of the current does not decrease, as in usual tunnel junctions, but remains approximately constant up to all considered bias voltages.
