We examine the ultrafast demagnetization process of iron-based materials, namely, Fe6 clusters and bulk bcc Fe, with time-dependent spin-density functional theory (TDSDFT). The magnetization continuity equation is reformulated and the torque due to the spin-current divergence is written in terms of an effective time-dependent kinetic magnetic field, an object already introduced in the literature. Its time evolution, as extracted from the TDSDFT simulations, is identified as one of the main sources of the local out-of-equilibrium spin dynamics and it plays a major role in the demagnetization process in combination with the spin orbit interaction. Such demagnetization is particularly strong in hot spots where the kinetic torque is maximized. Finally, we find the rate of demagnetization in Fe6 to be strongly dependent on the direction of polarization of the exciting electric field and this can be linked to the out-of-equilibrium distribution of the kinetic field in two comparative cases.

DOI: 10.1103/PhysRevB.95.024412

I. INTRODUCTION

The search for practical solutions for increasing the speed of manipulation of magnetic bits is essential for the progress of modern information and communication technology. It has been shown that there is an upper limit to the speed of the magnetization switching process when this is driven by a magnetic field [1,2]. An increase in power absorption beyond this limit and for higher magnetic-field amplitudes push a spin magnetization switching process when this is driven by a magnetic field [1,2], an object already introduced in the literature. Its time evolution, as extracted from the TDSDFT simulations, is identified as one of the main sources of the local out-of-equilibrium spin dynamics and it plays a major role in the demagnetization process in combination with the spin orbit interaction. Such demagnetization is particularly strong in hot spots where the kinetic torque is maximized. Finally, we find the rate of demagnetization in Fe6 to be strongly dependent on the direction of polarization of the exciting electric field and this can be linked to the out-of-equilibrium distribution of the kinetic field in two comparative cases.

A demonstration of the effect of the polarization of the electric field on the rate of demagnetization of Fe6 is discussed in Sec. IV. In Sec. V we show that previous observations for Fe6 are valid for bulk bcc Fe as well. We summarize in Sec. VI.
FIG. 1. (a) Typical electric-field pulse used to excite the Fe$_6$ cluster with the black arrow indicating the direction of the field. The fluence of this pulse is 580 mJ/cm$^2$. (b) Time evolution of the $z$ component of $B_{\text{ext}}$ and $B_S$ (exchange component of the field), with respect to their values at $t = 0$ integrated over the system volume $B_{\text{ext}}(t) = \mu_B \sum x B(t)$. (c) Time evolution of the variation of the total magnetization density $\Delta S^m(t) = \sum \Delta S^m(t)$ with respect to its initial value. (d) Time evolution on atomic site 6 of the magnetization density along z and of the electron density variation with respect to its value at $t = 0$ integrated inside a sphere of radius $R = 0.9$ Å.

In the Appendix we present a detailed derivation of the spin continuity equation.

II. THEORY

We consider the TDSDFT problem within the ALSDA for a spin-polarized system excited by an electric-field pulse. If one neglects second-order contributions arising from the solution of the coupled Maxwell-Schrödinger system of equations, the dynamics will be governed by the usual set of time-dependent Kohn-Sham (KS) equations

$$i\hbar \frac{d}{dt} \psi_{j}^{KS}(r, t) = H_{KS}(r, t) \psi_{j}^{KS}(r, t).$$

In Eq. (1) $\psi_{j}^{KS}(r, t)$ are the KS orbitals and the KS Hamiltonian $H_{KS}(r, t)$ can be expressed in the velocity gauge formulation and the minimal coupling substitution as

$$H_{KS}(r, t) = \frac{1}{2m} \left( -i\hbar \nabla - \frac{q}{c} A_{\text{ext}}(t) \right)^2 - \mu_B \mathbf{\sigma} \cdot \mathbf{B}_{\text{ext}}[n, \mathbf{m}](r, t) + v_{i}[n](r, t),$$

where

$$v_{i}[n](r, t) = \int d^3 r \frac{n(r')}{|r - r'|} + v_{\text{xc}}^{\text{ALSDA}}[n](r, t)$$

and

$$\mathbf{B}_{\text{ext}}[n, \mathbf{m}](r, t) = \mathbf{B}_{\text{xc}}^{\text{ALSDA}}[n, \mathbf{m}](r, t) + \mathbf{B}_{\text{ext}}(r, t).$$

Here $v_{i}(r, t)$ represents the usual noninteracting KS potential and the full noninteracting magnetic field $\mathbf{B}_{\text{ih}}(r, t)$ consists of the external one $\mathbf{B}_{\text{ext}}(r, t)$ and the exchange-correlation (XC) magnetic field $\mathbf{B}_{\text{xc}}^{\text{ALSDA}}(r, t)$. In the equations above $m$ is the electron mass, $q$ the electron charge, $c$ the speed of light, $\mathbf{a}_{\text{ext}}(t)$ the vector potential associated with the external magnetic field, $\mathbf{\sigma}$ the spin operator, $\mu_B$ the Bohr magneton, $n$ the electron density, and $\mathbf{m}$ the magnetization density. Then $v_{i}(r, t)$ is decomposed into a Hartree contribution, an XC correlation one $v_{\text{xc}}^{\text{ALSDA}}[n](r, t)$, and an ionic pseudopotential $V_{\text{pp}}(r - R_{l})$.

For a relativistic, norm-conserving pseudopotential the SO coupling enters the KS equations in the form [21]

$$V_{\text{pp}}^{I}(|r - R_{l}|) = \sum_{l} \left( V_{l}^{I}(r) + \frac{1}{4} V_{l}^{J,\text{SO}}(r) \right.$$

$$\left. + \sum_{n=-l}^{l} V_{l}^{J,\text{SO}}(r) \mathbf{L}_{l} \cdot \mathbf{S} |l,l,m\rangle \langle l,l,m| \right).$$

In Eq. (5) the orbital momentum operator associated with the $l$th atomic center is $\mathbf{L}_{l}$, while the vectors $|l,l,m\rangle$ are the associated set of spherical harmonics centered on that given atomic position. In Eq. (5) $V_{l}^{J,\text{SO}}(r)$ defines a generalized space-dependent SO coupling parameter providing a measure of the SO interaction strength close to the atomic site, while $V_{l}^{I}(r)$ includes all the ionic relativistic corrections such as the Darwin and the mass correction terms. Within the ALSDA $v_{\text{xc}}(r, t)$ and $\mathbf{B}_{\text{xc}}(r, t)$ are local functions in time of the electron density and magnetization, which in turn are written in terms of the time-dependent KS orbitals

$$n(r, t) = \sum_{j \in O} \sum_{\sigma} \psi_{j\sigma}^{KS}(r, t)^{*} \psi_{j\sigma}^{KS}(r, t),$$

$$\mathbf{m}(r, t) = \sum_{j \in O} \sum_{\alpha\beta} \psi_{j\alpha}^{KS}(r, t)^{*} \mathbf{\sigma}_{\alpha\beta} \psi_{j\beta}^{KS}(r, t),$$

where $O$ denotes occupied states. Starting from the set of time-dependent KS equations in (1), it is possible to derive an equation of motion for the magnetization, or a spin-continuity equation, in terms of the noninteracting KS observables. This reads

$$\frac{d}{dt} \mathbf{m}(r, t) = -\nabla \cdot \mathbf{J}_{\text{KS}}(r, t) + \mu_B \mathbf{m}(r, t) \times \mathbf{B}_{\text{ext}}(r, t)$$

$$+ \mathbf{T}_{\text{SO}}(r, t),$$

where $\mathbf{J}_{\text{KS}}(r, t)$ represents the noninteracting KS spin-current rank-2 tensor

$$\mathbf{J}_{\text{KS}}(r, t) = \frac{\hbar}{2mi} \sum_{j \in O} \left( \psi_{j\sigma}^{KS|i} \mathbf{\sigma} \psi_{j\sigma}^{KS} - \text{H.c.} \right)$$

and the SO torque contribution reads

$$\mathbf{T}_{\text{SO}}(r, t) = \sum_{l} \sum_{\alpha\beta} \sum_{j \in O} V_{l}^{\text{SO}}(|r - R_{l}|)$$

$$\times |\psi_{j\alpha}^{KS}| l, m_1, l \rangle |l, m_2, I \rangle \mathbf{L}_{l} |l, m_2, I \rangle \times \mathbf{\sigma}_{\alpha\beta}$$

$$\times |l, m_2, I | \psi_{j\beta}^{KS} \rangle.$$

(10)
The KS magnetic field $\mathbf{B}_\text{KS}(\mathbf{r},t)$ is taken as in Eq. (4), which in the absence of an external magnetic field reduces to $\mathbf{B}_{\text{XC}}(\mathbf{r},t)$. In DFT there is a set of zero-force theorems stating that the interaction between the particles cannot generate a net force [22]. In the case of the exchange-correlation magnetic field we have the exact condition $\int d^3 r \mathbf{m}(\mathbf{r},t) \times \mathbf{B}_{\text{XC}}(\mathbf{r},t) = 0$, which is satisfied by the ALSDA. Combining this equality with the assumption that the currents at the system boundary are negligible allows us to conclude that the only source of global spin loss is the SO coupling torque $\mathbf{T}_\text{SO}$ and that the spin lost during the temporal evolution is transferred to the orbital momentum of the system, which in turn is partially damped into the lattice (we consider frozen ions). Hence we have the relation

$$
\frac{d}{dt} \int_\Omega d^3 r \mathbf{m}(\mathbf{r},t) = \int_\Omega d^3 r \mathbf{T}_\text{SO}(\mathbf{r},t),
$$

where the integration extends over the entire volume $\Omega$.

Within the ALSDA, the exchange-correlation functional satisfies also a local variant of the zero-torque theorem [23], which is not a property of the exact DFT functional [24–26]. According to this condition, $\mathbf{m}(\mathbf{r},t) \times \mathbf{B}_{\text{XC}}(\mathbf{r},t) = 0$ and therefore the exchange-correlation magnetic field cannot contribute, even locally, to the magnetization dynamics. This leads us to conclude that the local magnetization dynamics is solely the result of the interplay between the spin-polarized currents and the SO torque (in reality $\mathbf{B}_{\text{XC}}$ can still contribute indirectly to the spin dynamics through a dynamical modification of the gap between up- and down-spin-polarized bands, which in turn may give rise to an enhancement of the spin dissipation via the spin-orbit-coupling channel). In order to elucidate this view further we make use of the hydrodynamical formalism applied to spin systems, which has already been introduced in Refs. [27,28]. This approach needs to be slightly modified in view of the fact that we are considering an effective single-particle Hamiltonian. By averaging over the number of electrons in the entire space we obtain

$$
\mathbf{S}_1 \cdot \mathbf{S}_2 \simeq \int_\Omega d^3 r n(\mathbf{r})\mathbf{s}(\mathbf{r} - \mathbf{d}/2) \cdot \mathbf{s}(\mathbf{r} + \mathbf{d}/2).
$$

Then, by expanding the spin density in a Taylor series up to second order over the distance $d$ and then neglecting the zeroth-order contribution (we focus our attention on the nonlocal term appearing in the expansion), after some straightforward rearrangement we arrive at

$$
\mathbf{S}_1 \cdot \mathbf{S}_2 \simeq -\frac{d^2}{4} \int_\Omega d^3 r n(\mathbf{r})\left[ -\nabla \cdot \mathbf{n}(\mathbf{r})\mathbf{s}(\mathbf{r}) \cdot \nabla \mathbf{s}(\mathbf{r}) \right].
$$

Finally, by considering a sufficiently large integration volume, the use of the divergence theorem allows us to neglect all the boundary terms with the consequent final expression

$$
\mathbf{S}_1 \cdot \mathbf{S}_2 \simeq -\frac{d^2}{4} \int_\Omega d^3 r \left[ \frac{\nabla n(\mathbf{r}) \cdot \nabla s(\mathbf{r})}{n(\mathbf{r})} + \nabla^2 s(\mathbf{r}) \right],
$$

which remarkably resembles the result in Eq. (13) for the kinetic magnetic field. We can therefore tentatively interpret $\mathbf{B}_\text{kin}(\mathbf{r},t)$ as an effective mean-field internal magnetic field, which plays a role in coupling the spins at different locations in the system analogously to the Heisenberg spin-spin interaction.

[see Eq. (A25)]

$$
\mathbf{B}_\text{kin}(\mathbf{r},t) = \frac{1}{f^2} \left[ \frac{\nabla n \cdot \nabla \mathbf{s}}{n} + \nabla^2 \mathbf{s} \right],
$$

with spin vector field $\mathbf{s}(\mathbf{r},t) = \frac{\mathbf{m}(\mathbf{r},t)}{n(\mathbf{r})}$.

Such a $\mathbf{B}_\text{kin}(\mathbf{r},t)$ field has only an instrumental role in the equations of motion for the spin density; a very similar expression was already introduced in some previous work. In Ref. [19] it is expressed in the form $\dot{\mathbf{k}} = \frac{\mathbf{m}(\mathbf{r},t) \times \mathbf{h}(\mathbf{r},t)}{n(\mathbf{r})}$, while in Ref. [20] it appears as $\frac{\nabla \mathbf{v}_\text{m}}{n}$. The interpretation of $\mathbf{B}_\text{kin}$ may look quite obscure at first, however, in Refs. [29,30] it was identified as a possible source of spin-wave excitations in the form of a spin-spin interaction potential.

In order to clarify this point, let us consider the Heisenberg interaction between two spins centered on atoms placed at a distance $d = |\mathbf{d}|$. We can assume naively, but reasonably, that the spin-spin interaction between the two spin distributions, computed at an arbitrary point $\mathbf{r}$ in space, may be expressed in the form

$$
H_{\text{eff}}(\mathbf{r}) \simeq \mathbf{s}(\mathbf{r} - \mathbf{d}/2) \cdot \mathbf{s}(\mathbf{r} + \mathbf{d}/2).
$$

where it is more convenient for us to employ a spin field $\mathbf{s}(\mathbf{r})$, which describes the spin distribution in space, instead of an atom localized spin vector. Hence, $H_{\text{eff}}$ defines an effective single-particle Hamiltonian. Finally, by considering a sufficiently large integration volume, the use of the divergence theorem allows us to neglect all the boundary terms with the consequent final expression

$$
\mathbf{S}_1 \cdot \mathbf{S}_2 \simeq \int_\Omega d^3 r \left[ -\nabla \cdot \mathbf{n}(\mathbf{r})\mathbf{s}(\mathbf{r}) \cdot \nabla \mathbf{s}(\mathbf{r}) \right].
$$

which remarkably resembles the result in Eq. (13) for the kinetic magnetic field. We can therefore tentatively interpret $\mathbf{B}_\text{kin}(\mathbf{r},t)$ as an effective mean-field internal magnetic field, which plays a role in coupling the spins at different locations in the system analogously to the Heisenberg spin-spin interaction.
III. ANALYZING SPIN DYNAMICS FROM TDS-DFT SIMULATIONS IN THE Fe6 CLUSTER

Here we present the results of TDS-DFT calculations, performed with the OCTOPUS code [31], where we simulate the ultrafast demagnetization process in iron-based ferromagnetic systems. In all those, at time \( t = 0 \) the system is in its ground state. Then we apply an intense electric-field pulse with a duration of less than 10 fs, which initiates the dynamics. The pseudopotentials for Fe used in the calculations are fully relativistic, norm conserving, and generated using a multireference-pseudopotential scheme [32] at the level implemented in APE [33,34], which takes directly into account the semicore states. For the XC functional we employ the ALSDA with parametrization from Perdew and Wang [35]. Our simulations then consist in evolving in time the KS wave functions, i.e., in solving numerically the set of equations (1). The results are then interpreted through the magnetization continuity equation (12).

In Fig. 1 the extracted magnetization dynamics of a Fe6 magnetic cluster is presented. We use the LSDA ground-state geometry of Fe6 as extracted from Refs. [36,37] for which we reproduce the reported therein spin state \( S = 20h/2 \). The nuclei are kept stationary during the dynamics. In Fig. 1(c) we observe that the total loss of the \( z \) component of the total magnetization \( S_z^{tot}(t) \) is exactly equal to the variation in value of its module \( |S^{tot}| \) since the global noncollinear contribution is negligible. This indicates that the spin is not exchanged globally between the different components of the magnetization vector, but, according to Eq. (11), it is at least partially transferred into the orbital momentum of the system. We note that, due to the electrostatic interactions with the nuclei and due to the interaction with the laser field, the rotational invariance of the electronic system is broken and the total angular momentum is not conserved.

In Fig. 1(b) we observe that the average kinetic magnetic field (over the entire simulation box, for \( F = 1 \)) is comparable in magnitude to the exchange component. At the same time, \( B_{kin, z}^{tot} \) shows a much more oscillatory behavior compared to \( B_{X, z} \). In particular, while \( B_{X, z}^{tot} \) evolves smoothly in time following the action of the optical excitation, \( B_{kin, z}^{tot} \) presents an abrupt variation at the onset of the electrical pulse. This is due to the fact that the laser pulse directly excites currents, through the term \(-\nabla \cdot D_r r, t\) in Eq. (12), which in turn produces a modification of the gradients of the charge/spin density, even on a global scale since they are not conserved. Thus we observe large variations of \( B_{kin, z}^{tot} \). In addition, \( B_{X, z} \) can also oscillate very strongly locally, following the temporal variation of the densities, but in the evaluation of \( B_{X, z}^{tot} \), these oscillations are averaged out given that the densities are approximately conserved over the entire simulation box. During the action of the pulse we see a tendency of the two fields to compensate each other, an effect strongly resembling the Lenz law. After the pulse, \( B_{kin} \) continues to oscillate dramatically with its average value, only slowly increasing. In contrast, \( B_{X, z}^{tot} \) decreases (in absolute value) due the net dissipation of spin angular momentum.

Moving from an analysis of global quantities to probing locally the spin dynamics, in Fig. 1(d) we compare the magnetization and the electron density around atomic site 6 at the tip of the cluster [see inset of Fig. 1(a) for the numbering of all the cluster atoms]. We define local magnetization and charge associated with the particular atomic site \( I \) as

\[
\begin{align*}
S^I(t) &= \frac{1}{|S^{tot}|} \int_{S_R} d^3 r \, m(r, t), \\
Q^I(t) &= \frac{1}{|S^{tot}|} \int_{S_R} d^3 r \, n(r, t),
\end{align*}
\]

where the integration volume \( S_R \) is a sphere of radius \( R \) centered at site \( I \). Our results show that the loss of \( S^I_z \) is not taking place just during the action of the external pulse, but it is rather distributed over the entire time evolution. This suggests that the spin-sink mechanism is not directly related to the coupling of the system to the laser field, but is rather intrinsic to the electron dynamics following the pulse. Furthermore, close to the atomic site, the temporal variation of the charge \( Q^I \) is much smaller in magnitude and smoother than that of \( S^I \). In addition, for long times \( Q^I \) settles close to an average value, while \( S^I \) continues to decrease. Hence the long-term spin dynamics is not the result of a net charge displacement from the region close to the ions to the interstitial space. These observations are valid for all the atomic sites in the cluster.

If we now consider the continuity equation for the electron density (see the Appendix for further explanation)

\[
\frac{D}{Dt} n(r, t) = -n(r, t) \nabla \cdot v(r, t),
\]

where \( \frac{D}{Dt} n(r, t) \) is the material derivative of the electron density

\[
\frac{D}{Dt} n(r, t) = \left( \frac{d}{dt} + v \cdot \nabla \right) n(r, t).
\]

From Fig. 1(d) we observe that during the action of the pulse the density variation in the vicinity of the atoms appears to be very small compared to the magnetization variation. We can therefore safely assume that in this spatial region \( n(r, t) \approx 0 \), with at the same time \( n(r, t) \neq 0 \). From these considerations we deduce that \( v(r, t) \approx 0 \) is a reasonably good approximation for the velocity field in the vicinity of the atoms (this does not imply that the velocity field is exactly zero, but only that its effect on the spin dynamics in this particular case is negligible). The same argument is valid also for the state resolved density \( n_j(r, t) \), given that \( n(r, t) = \sum_{j \in \mathbb{Z}} n_j(r, t) \), the contribution of the local time derivative of the Kohn-Sham state density can be neglected. By applying the latter in Eq. (12) we finally obtain a relation that can be considered approximately valid in this spatial region of the simulation box,

\[
\frac{d}{dt} m(r, t) \simeq -\nabla \cdot D + \mu_B m \times B_{kin} + T_{SO},
\]

where the contribution to the spin dynamics due to the velocity-field term has been neglected. Note that here we have also used the condition \( m(r, t) \times B_{SC}(r, t) = 0 \), which is consequential to the LSDA. In addition, the decay of \( B_{SC} \) during the evolution, is not so significant as to produce a dynamical modification of the gap between up- and down-spin states.

In Fig. 2 we compare the behavior of the kinetic field and of the local magnetization at two atomic sites, respectively: 1 (one of the atoms in the base plane of the bipyramid) and 6 (an atom at one of the apexes). It can be seen from Fig. 2(a) that these two
sites present different rates of demagnetization. In particular, at site 6 the spin decay is considerably more prominent with respect to that observed at site 1. In contrast, the fluctuations in $S_{r}(t)$ are significantly more pronounced for site 1 than for site 6. This can be understood from the fact that we have chosen an electric pulse with polarization vector in the basal plane of the bipyramid. As such, the charge fluctuations for the atoms in the basal plane are expected to be much larger than those of the apical atoms. Finally, we note that $B_{r}^{\text{kin}}(t)$ follows similar qualitative trends as $S_{r}(t)$ [see Fig. 2(b)]. In fact, the average change following the excitation pulse is larger for site 6 (the one experiencing the larger demagnetization), but the fluctuations are more pronounced for site 1 [the one experiencing the larger fluctuations in $S_{r}(t)$].

The correlation between the kinetic field and the magnetization loss is also rather evident in Fig. 3. There the time-averaged variations in the $x$ component of the two fields $\mathbf{m} \times \mathbf{B}_{\text{kin}}$ and $\mathbf{m}(r,t)$ are clearly comparable in magnitude and localized over the same regions of the simulation box. This demonstrates that the kinetic field can be considered as the main force driving the noncollinearity during the spin evolution. The fact that the contrast is stronger at the apex atoms (hot spots for demagnetization) agrees with Fig. 2(a), while the dipole-type patterns indicate how the longitudinal spin decays preserving global collinearity. The correlation between the $z$ components of $\mathbf{m} \times \mathbf{B}_{\text{kin}}$ and $\mathbf{m}(r,t)$ is not as evident as that for the transverse component $x$. This is due to the fact that the $x$ and $y$ components of the field are much smaller compared to the $z$ one. Furthermore, the contribution to the spin dynamics along $z$ of the SO coupling, together with the internal dissipative term due to the spin currents, cannot be neglected.

In order to quantify the local noncollinearity we examine the evolution of the misalignment angle $\theta$ between the $z$ axis and the direction of the magnetic fields (averaged over spheres). It can be seen in Fig. 4 that at site 1 the averaged kinetic field and the local spin deflect very little from the quantization axis and remain rather parallel to each other. The angle that $\mathbf{B}_{\text{kin}}^{I}(t)$ forms with the magnetization direction (the $m_{I}$ direction) is practically negligible. Instead, at site 6, $\mathbf{B}_{\text{kin}}^{I}(t)$ shows a significant deflection from the $z$ axis after the first 5 fs of the

![Graph](Image)
According to Fig. 4, in the case of Fe6, the direction in the direction of the spin vector by construction, and JACOPO SIMONI, MARIA STAMENOVA, AND STEFANO SANVITO PHYSICAL REVIEW B 95, 024412 (2017)

The connection field \( \mathcal{A}(r,t) \) provides a measure of the amount of noncollinearity accumulated in the translation of the spin vector from \( \mathbf{r} \) to \( \mathbf{r} + d\mathbf{r} \) while keeping the axes in the spin space fixed,

\[
D_s \mathbf{s}(\mathbf{r},t) = D_s \mathbf{r}(t) + \mathcal{A}_i(t) \times \mathbf{s}(t). 
\] (23)

The connection field \( \mathcal{A}(r,t) \) provides a measure of the amount of noncollinearity accumulated in the translation of the spin vector from \( \mathbf{r} \) to \( \mathbf{r} + d\mathbf{r} \).

By using the previous expression to rewrite the first- and second-order spatial derivatives, the kinetic field of Eq. (13) can be divided into two components

\[
\mathbf{B}_{\text{kin}}(\mathbf{r},t) = \mathbf{B}_{\text{kin}}^0(\mathbf{r},t) + \delta \mathbf{B}_{\text{kin}}(\mathbf{r},t). 
\] (24)

Here we have introduced

\[
\mathbf{B}_{\text{kin}}^0(\mathbf{r},t) = \frac{1}{Fe} \left[ \nabla n(\mathbf{r},t) \cdot D_s \mathbf{r}(t) + D^2 s(\mathbf{r},t) \right], 
\] (25)

which has no effect on the dynamics, having locally the same direction of the spin vector by construction, and

\[
\delta \mathbf{B}_{\text{kin}}(\mathbf{r},t) = \frac{1}{Fe} \sum_{i=1}^{3} \left[ \frac{d_n}{n} \left( -s^2 A_i + (s \cdot A_i)s \right) - 2[s^2 d_i A_i - (s \cdot A_i)s] - 2[A_i(s \cdot D_s s) - D_i(s \cdot A_i)] + 4(s \times A_i)(s \cdot A_i) \right]. 
\] (26)

According to Fig. 4, in the case of Fe6, the direction in the spin space of the connection tensor \( \mathcal{A}_i \) for every \( i \) component can be considered in a first approximation orthogonal to the direction of the spin vector \( \mathbf{s}(\mathbf{r},t) \), since its component along \( z \) is considerably smaller than the components along \( x \) and \( y \). From this we could assume that \( s \cdot A_i \approx 0 \) and we obtain the following simplified expression for \( \delta \mathbf{B}_{\text{kin}}(\mathbf{r},t) \):

\[
\delta \mathbf{B}_{\text{kin}}(\mathbf{r},t) = \frac{1}{Fe} \sum_{i=1}^{3} \left[ \left( -\frac{d_n}{n} s^2 - 2 s \cdot D_s s \right) \mathcal{A}_i \right]. 
\] (27)

This represents the part of \( \mathbf{B}_{\text{kin}} \) that gives rise to a nonzero torque in Eq. (22).

Analogous conclusions arise from the introduction of the concept of parallel transport, commonly used in differential geometry. This requires a proper definition of the covariant derivative obtained by comparing \( \mathbf{s}(\mathbf{r} + d\mathbf{r}) \) not with \( \mathbf{s}(\mathbf{r}) \), but with the value that the spin vector would have if it was translated from \( \mathbf{r} \) to \( \mathbf{r} + d\mathbf{r} \) while keeping the axes in the spin space fixed,

\[
D_s \mathbf{s}(\mathbf{r},t) = D_s \mathbf{r}(t) + \mathcal{A}_i(t) \times \mathbf{s}(t). 
\] (23)

The connection field \( \mathcal{A}(r,t) \) provides a measure of the amount of noncollinearity accumulated in the translation of the spin vector from \( \mathbf{r} \) to \( \mathbf{r} + d\mathbf{r} \) while keeping the axes in the spin space fixed,

\[
D_s \mathbf{s}(\mathbf{r},t) = D_s \mathbf{r}(t) + \mathcal{A}_i(t) \times \mathbf{s}(t). 
\] (23)

The connection field \( \mathcal{A}(r,t) \) provides a measure of the amount of noncollinearity accumulated in the translation of the spin vector from \( \mathbf{r} \) to \( \mathbf{r} + d\mathbf{r} \) while keeping the axes in the spin space fixed,

\[
D_s \mathbf{s}(\mathbf{r},t) = D_s \mathbf{r}(t) + \mathcal{A}_i(t) \times \mathbf{s}(t). 
\] (23)

The connection field \( \mathcal{A}(r,t) \) provides a measure of the amount of noncollinearity accumulated in the translation of the spin vector from \( \mathbf{r} \) to \( \mathbf{r} + d\mathbf{r} \) while keeping the axes in the spin space fixed,

\[
D_s \mathbf{s}(\mathbf{r},t) = D_s \mathbf{r}(t) + \mathcal{A}_i(t) \times \mathbf{s}(t). 
\] (23)

The connection field \( \mathcal{A}(r,t) \) provides a measure of the amount of noncollinearity accumulated in the translation of the spin vector from \( \mathbf{r} \) to \( \mathbf{r} + d\mathbf{r} \) while keeping the axes in the spin space fixed,
already present in the ground-state configuration. What really differs is the amount of intersite noncollinearity concentrated in the out-of-plane region. In the E\text|x\text case, if we examine the angle between $\mathbf{B}_{\text{kin}}(r,t)$ and $\mathbf{m}(r,t)$ averaged in time over entire simulation along one particular cross-section plane (vertical through the base diagonal of the cluster as depicted in the inset), one can observe, in particular in the out-of-plane interstitial regions, a significantly larger amount of noncollinearity of the spin vector density, accumulating in the case of faster demagnetization.

Notably, there is a change in the symmetry between Figs. 5(c) and 5(e): In both cases no significant spin noncollinearity arises in the plane parallel to the field connecting the atomic centers. It is, however, important to notice that the amount of intrasite spin noncollinearity for the in-plane atoms is strongly dependent on the polarization direction of the applied laser field. In fact, in the case of E\text|z\text the temporally averaged angle between $\mathbf{s}$ and $\mathbf{B}_{\text{kin}}$ appears much higher with respect to the one computed in the E\text|z\text case. Figure 5(d) and 5(f) show that the non-collinear to $\mathbf{B}_{\text{kin}}$ spin density also quickly decays in the interatomic regions where the charge density is inherently lower.

Although $\mathbf{B}_{\text{kin}}$ is not the only torque generator and the SO contribution is significant too, the former plays a role in deflecting the spins in the system in a manner that correlates with the rate of global demagnetization. Importantly, our simulations clearly show that the demagnetization process is very anisotropic and particular directions of the exciting electric field may enhance the rate of demagnetization (this is only a demonstration of principle and the study of these effects is beyond the scope of this paper).

V. DEMAGNETIZATION OF bcc Fe

Finally, we present results of analogous simulations in bulk materials, namely, in bcc Fe, with the aim of demonstrating the qualitative universal role played by $\mathbf{B}_{\text{kin}}$ in the ultrafast demagnetization process. We consider bcc Fe in its ferromagnetic phase with total spin in the unit cell $S = 4.85h/2$ and with two atoms in it.

We employ a lattice parameter $a = 2.9\ \AA$, with a $4 \times 4 \times 4$ k-point grid. In Fig. 6(a) we show the demagnetization rate of the single unit cell after it has been excited with the electric-field pulse [Fig. 6(a)]. The green curve represents the demagnetization computed inside the unit cell and resembles in shape the sum of the magnetization variation $\sum J \Delta S_{J}(t)$ calculated in the vicinity of the two Fe atoms, even if it is different in magnitude. This suggests that a large amount of spin is driven outside from the atomic integration region during the evolution. Similarly to the cluster, the dynamics of the on-site magnetization can be described in terms of a two-step process with an initial fast decay during the action of the external pulse, followed by a slower and noisy decrease in magnitude. The first fast decay may be attributed to the effect of the SO enhanced by the collapse of the effective field $\mathbf{B}_{\text{eff}}$ following the action of the laser pulse. In Fig. 6(b) the collapse after the first 5 fs of the $z$ component of the effective field is quite clear, even if it appears to be more pronounced for the kinetic field $B_{\text{kin},z}(t)$ with respect to the exchange field $B_{\text{ex},z}(t)$. Similarly to the case of Fe$_6$, the role played by $\nabla \cdot \mathbf{D}(r,t)$ is dominant during the action of the pulse, but after this initial phase the dynamics is dominated by intraband transitions and the interplay between the spin-orbit coupling and the effective field $\mathbf{B}_{\text{eff}}$ becomes dominant.

Figure 6(d) shows the evolution of the noncollinearity of the spin vector $\sum J \Delta S_{J}(t)$ and of the kinetic field $\sum J B_{\text{kin},z}(t)$. The level of correlation among the two quantities confirms the importance of the kinetic field in the evolution of the spin noncollinearity. The long tail of spin dissipation may be explained in terms of intraband spin-up/spin-down transitions through an Elliott-Yafet type of mechanism triggered by the scattering with the effective field $\mathbf{B}_{\text{eff}}$.

\[ A_{i \rightarrow f} = \langle \Psi_{n,k} | \hat{\sigma} \cdot \mathbf{B}_{\text{eff}} | \Psi_{n,k} \rangle \]  

(28)

Here $A_{i \rightarrow f}$ represents the transition amplitude between two states with different $\mathbf{k}$ vector and in the presence of SO coupling with different mixing of up- and down-spin components.

VI. CONCLUSION

In conclusion, we state the central result of our work, namely, that the equation of motion for the spin dynamics within the ALSDA of TDSDFT [see Eq. (8)] can be rewritten in the form of Eq. (12), by using a formalism borrowed from magnetohydrodynamics. We have analyzed the properties of the so-called kinetic magnetic field $\mathbf{B}_{\text{kin}}$ and its role in the ultrafast demagnetization process in two different systems: a ferromagnetic Fe$_6$ cluster and bulk bcc Fe. The role of this field is particularly significant for processes far from equilibrium, such as the ultrafast demagnetization observed in transition metals.

In both systems studied the spin dynamics is the result of the interplay between the SO coupling and $\mathbf{B}_{\text{kin}}(r,t)$, which,
in general, is strongly coupled to the external pulse and highly nonuniform in space. We have shown that the spin loss locally correlates with $B_{\text{kin}}(r,t)$. Through the concept of parallel transport and the definition of a connection tensor $A_i$, we have gained further insight into the evolution of the spin texture. As $A_i$ describes the degree of spin rotation per infinitesimal spatial translation, it also provides a measure for the misalignment between the kinetic field and the spin texture. The regions with higher $\| A_i \|$ correspond to stronger local demagnetization.

Finally, the effect of the direction of the polarization vector of the electric-field pulse has been studied for Fe$_6$. We have found that clusters will demagnetize about twice as fast if the polarization vector is in the base plane and not vertical (through the apex atoms). Our analysis has shown a significant increase in the noncollinearity between $B_{\text{kin}}(r,t)$ and the spin density in the fast demagnetizing case. Such anisotropy, due to the electric dipole matrix elements for the valence electrons, is likely to occur in crystalline systems as well. During the application of the laser pulse, the rise of spin noncollinearity may be enhanced by the particular polarization direction of the laser pulse through the spin-orbit coupling and this effect combined with the collapse of the kinetic field may explain the initial spin loss. However, in both Fe$_6$ and bcc Fe the magnetization loss is more prominent after the laser pulse has been reduced to zero. During this second phase of spin dissipation we anticipate microscopic differences between the on-site intrinsic spin noncollinearity near the atomic sites.

APPENDIX: DERIVATION OF THE HYDRODYNAMIC CONTINUITY EQUATION

In this Appendix we show in some detail how Eq. (12) can be obtained by starting from the standard TDSDFT continuity equation (8). Here we follow the hydrodynamical formalism of quantum mechanics, where a single particle with spin is considered equivalent to a nonlinear vector field. In this type of hydrodynamics the quantum effects are separated as nonlinear terms and are described through effective quantum potentials (see Ref. [29]).

The formalism is based on the assumption that it is possible to describe the dynamical evolution of a single particle immersed in an external vector potential $A(r,t)$ through the so-called Madelung decomposition (see Ref. [38]) of the system wave function, in which the amplitude is translated into the probability density and the gradient of the phase determines the velocity field. A hydrodynamical description of the wave function was also obtained in Ref. [39] starting from the ordinary interpretation of quantum mechanics and by introducing an operator for the charge density and the current density.

The formalism was also later extended to the semirelativistic description (Pauli approximation) of a single particle in an external electromagnetic field in Ref. [27]. However, while in all the previous studies the main objective was to derive the single-particle dynamics of the spin-1/2 plasma, only recently has the study of the collective dynamical properties of the quantum plasma started to attract some interest (see Refs. [28,40]).

In deriving Eq. (12) for the spin density in the Kohn-Sham system we introduce also of the electron density $n(r,t)$ and the velocity field $\mathbf{v}(r,t)$. The equation of motion for the velocity field is not explicitly written here for the reasons explained in Sec. III.

The electron density is written in terms of the Kohn-Sham wave functions $\psi_{j}^{\text{KS}}(r,t)$ as

$$n(r,t) = \sum_{j \in \mathcal{O}} \psi_{j}^{\text{KS}}(r,t) \psi_{j}^{\text{KS}}(r,t)^{\dagger},$$

(A1)

while the spin density is

$$n_s(r,t) = \sum_{j \in \mathcal{O}} \sigma_j \psi_{j}^{\text{KS}}(r,t) \psi_{j}^{\text{KS}}(r,t)^{\dagger},$$

(A2)

and the covariant velocity field appears as

$$\mathbf{v}(r,t) = \frac{\hbar}{2mi} \sum_{j \in \mathcal{O}} \left[ \psi_{j}^{\text{KS}}(r,t) \nabla \psi_{j}^{\text{KS}}(r,t)^{\dagger} - \psi_{j}^{\text{KS}}(r,t)^{\dagger} \nabla \psi_{j}^{\text{KS}}(r,t) \right] - \frac{e}{mc} A(r,t).$$

(A3)

By making use of the Kohn-Sham equations (1) the charge continuity equation can be written straightforwardly as

$$\frac{d}{dt} n(r,t) = - \frac{\hbar}{2mi} \nabla \cdot \sum_{j \in \mathcal{O}} \left[ \psi_{j}^{\text{KS}}(r,t) \nabla \psi_{j}^{\text{KS}}(r,t)^{\dagger} - \psi_{j}^{\text{KS}}(r,t)^{\dagger} \nabla \psi_{j}^{\text{KS}}(r,t) \right] + \frac{e}{mc} \nabla \cdot [n A(r,t)],$$

(A4)

while for spin it is written in terms of $n(r,t)$ and $n_s(r,t)$ as

$$\frac{d}{dt} n_s(r,t) = - \frac{\hbar^2}{4mi} \nabla \cdot \sum_{j \in \mathcal{O}} \left[ \psi_{j}^{\text{KS}}(r,t) \nabla \psi_{j}^{\text{KS}}(r,t)^{\dagger} - \psi_{j}^{\text{KS}}(r,t)^{\dagger} \nabla \psi_{j}^{\text{KS}}(r,t) \right] + \frac{e}{mc} \sum_{j} \partial_j [n \psi_{j}^{\text{KS}}(r,t) - \mu_B n (s \times B_{\text{XC}}) + T_{\text{SO}}].$$

(A5)
In order to simplify the formalism we employ the notation

$$ns_i \partial s_k = s_i \sum_{j \in O} \left[ \partial_i \psi_j^{KS}(r,t) \partial_j \psi_j^{KS} + \psi_j^{KS}(r,t) \partial_i \partial_j \psi_j^{KS} \right] - \partial n s_i \cdot s_k. \quad (A6)$$

We now need to focus our attention on the first term on the right-hand side of Eq. (A6), by using the notation

$$\mathcal{F}_i(r,t) = s_i \sum_{j \in O} \left[ \nabla \psi_j^{KS}(r,t) \partial_j \psi_j^{KS} + \psi_j^{KS}(r,t) \partial_j \nabla \psi_j^{KS} \right], \quad (A7)$$

which leads to

$$\mathcal{F}_i(r,t) = \frac{1}{\hbar} \sum_{j,r \in O} \left[ \psi_j^{KS} \partial_j \psi_j^{KS} \nabla \psi_j^{KS} + \psi_j^{KS} \partial_j \nabla \psi_j^{KS} \right]. \quad (A8)$$

The antisymmetric part $K_{ik}(r,t)$ of the tensor $\mathcal{F}_i(r,t)$, defined as $K_{ik} = \mathcal{F}_i - (i \leftrightarrow k)$, may be written as

$$K_{ik}(r,t) = \frac{1}{\hbar} \sum_{j,r \in O} \sum_{\alpha,\beta,\alpha',\beta'} \left[ \psi_{r,\alpha}^{KS} \psi_{r,\alpha'}^{KS} \alpha_{\alpha',\beta'}^{[i]} \partial_j \psi_{j,\beta'}^{KS} + \psi_{j,\alpha}^{KS} \psi_{j,\alpha'}^{KS} \alpha_{\alpha',\beta'}^{[i]} \partial_j \psi_{j,\beta'}^{KS} \right]. \quad (A9)$$

By making use of the relation between Pauli matrices (see Ref. [29])

$$\alpha_{\alpha',\beta'}^{[i]} = i \sum_s \epsilon_{iks} \left[ \alpha_{\alpha',\beta}^{s} - \delta_{\alpha,\beta} \alpha_{\alpha',\beta}^{s} \right], \quad (A10)$$

we obtain the final expression for $K_{ik}$ that can be split into two parts,

$$K_{ik}(r,t) = \sum_{j,r \in O} K_{ik}^{(i,r)}(r,t) + \sum_{j \neq j' \in O} K_{ik}^{(i,j')} \delta_{r,r'} + \sum_{j \in O} K_{ik}^{(i,j)}(r,t), \quad (A11)$$

where we have introduced the tensor

$$K_{ik}^{(i,j)}(r,t) = i \sum_{j,r \in O} \sum_{\alpha,\beta,\alpha',\beta'} \epsilon_{iks} \left[ \psi_{r,\alpha}^{KS} \psi_{j,\alpha}^{KS} \alpha_{\alpha',\beta'}^{[i]} \partial_j \psi_{j,\beta'}^{KS} \right] + \frac{2m_e}{\hbar} \sum_{j,r \in O} \sum_{\alpha,\beta,\alpha',\beta'} \epsilon_{iks} \left[ \psi_{r,\alpha}^{KS} \alpha_{\alpha',\beta'}^{[i]} \partial_j \psi_{j,\beta'}^{KS} \right] \left[ \mathbf{v}_j(r,t) + \frac{e}{mc} \mathbf{A}(r,t) \right]$$

$$+ \frac{\hbar}{2F_m} \sum_{j \neq j' \in O} \sum_{\alpha,\beta,\alpha',\beta'} \epsilon_{iks} \left[ \psi_{r,\alpha}^{KS} \psi_{j,\alpha}^{KS} \alpha_{\alpha',\beta'}^{[i]} \partial_j \psi_{j,\beta'}^{KS} \right] \left[ \mathbf{v}_j(r,t) + \frac{e}{mc} \mathbf{A}(r,t) \right]. \quad (A12)$$

The procedure that we have followed up to now is formally exact. Then, in order to simplify the previous expression we substitute the Kohn-Sham ratio $F_j = \frac{\psi^{KS\dagger} \psi^{KS}}{n(r,t)}$, with its average over the various occupied states $\mathcal{F}_j \simeq \bar{F} = \frac{\langle \psi^{KS\dagger} \psi^{KS} \rangle}{n(r,t)}$. From the fact that, to a good degree of approximation, $\bar{F} \simeq \frac{1}{N}$ with $N$ total number of particles in the system, we will consider from now on $\bar{F}$ to be spatially homogeneous and constant in time.

Then Eq. (A11) becomes

$$K_{ik}(r,t) = i \bar{F} \sum_{j,r \in O} \sum_{\alpha,\beta,\alpha',\beta'} \epsilon_{iks} \left[ \psi_{r,\alpha}^{KS} \psi_{j,\alpha}^{KS} \alpha_{\alpha',\beta'}^{[i]} \partial_j \psi_{j,\beta'}^{KS} \right] + \frac{2m_e}{\hbar} \sum_{j,r \in O} \sum_{\alpha,\beta,\alpha',\beta'} \epsilon_{iks} \left[ \psi_{r,\alpha}^{KS} \alpha_{\alpha',\beta'}^{[i]} \partial_j \psi_{j,\beta'}^{KS} \right] \left[ \mathbf{v}_j(r,t) + \frac{e}{mc} \mathbf{A}(r,t) \right]$$

$$+ \frac{\hbar}{2F_m} \sum_{j \neq j' \in O} \sum_{\alpha,\beta,\alpha',\beta'} \epsilon_{iks} \left[ \psi_{r,\alpha}^{KS} \psi_{j,\alpha}^{KS} \alpha_{\alpha',\beta'}^{[i]} \partial_j \psi_{j,\beta'}^{KS} \right] \left[ \mathbf{v}_j(r,t) + \frac{e}{mc} \mathbf{A}(r,t) \right]. \quad (A13)$$

In order to simplify the formalism we employ the notation $K_{ik,j}(r,t) = n(s_i \partial_j s_k - s_k \partial_j s_i)$. Immediately from Eq. (A13) it follows that

$$\frac{\hbar}{2F_m} n(s_i \partial_j s_k - s_k \partial_j s_i) = - \sum_{j \in O} \sum_{\alpha,\beta,\alpha',\beta'} \epsilon_{iks} J_{KS}^{(\alpha)}(r,t) + \sum_{j \in O} \sum_{\alpha,\beta,\alpha',\beta'} \epsilon_{iks} \left[ \psi_{r,\alpha}^{KS} \psi_{j,\alpha}^{KS} \alpha_{\alpha',\beta'}^{[i]} \partial_j \psi_{j,\beta'}^{KS} \right] \left[ \mathbf{v}_j(r,t) + \frac{e}{mc} \mathbf{A}(r,t) \right]$$

$$+ \frac{\hbar}{2F_m} \sum_{j \neq j' \in O} \sum_{\alpha,\beta,\alpha',\beta'} \epsilon_{iks} \left[ \psi_{r,\alpha}^{KS} \psi_{j,\alpha}^{KS} \alpha_{\alpha',\beta'}^{[i]} \partial_j \psi_{j,\beta'}^{KS} \right] \left[ \mathbf{v}_j(r,t) + \frac{e}{mc} \mathbf{A}(r,t) \right]. \quad (A14)$$

where $\mathbf{m}_j$ and $\mathbf{v}_j$ define, respectively, the single Kohn-Sham state magnetization and velocity field. By employing the properties of the Levi-Civita tensor we have

$$\frac{\hbar}{2F_m} (ns \times \hat{s})^\alpha = - J_{KS}^{(\alpha)}(r,t) + \sum_{j \in O} \sum_{\alpha,\beta,\alpha',\beta'} \epsilon_{iks} \left[ \psi_{r,\alpha}^{KS} \psi_{j,\alpha}^{KS} \alpha_{\alpha',\beta'}^{[i]} \partial_j \psi_{j,\beta'}^{KS} \right] \left[ \mathbf{v}_j(r,t) + \frac{e}{mc} \mathbf{A}(r,t) \right] + D_{\alpha}(r,t). \quad (A15)$$

where we have introduced the new tensor quantity

$$D(r,t) = - \sum_{j \in O} \sum_{\alpha,\beta,\alpha',\beta'} \left[ \mathcal{F}_{ij}(r,s) - \mathcal{F}_{ij} \mathbf{m}_j(r,s) \right] \cdot \left[ \mathbf{v}_j(r,t) + \frac{e}{mc} \mathbf{A}(r,t) \right] \cdot \left[ \mathbf{v}_j(r,t) + \frac{e}{mc} \mathbf{A}(r,t) \right]. \quad (A16)$$
Here $\mathcal{F}_{ij} = \frac{\psi_{KS}^{i} \phi_{KS}^{j}}{n(r,t)}$ and the other many-particle objects are defined as

$$\mathcal{J}^{(j,r)}(r,t) = -\frac{i\hbar}{2m} [\psi_{j}^{\dagger} \mathbf{V} \psi_{j}^{KS} - \mathbf{V} \psi_{j}^{KS} \psi_{j}^{\dagger}], \quad (A17)$$

$$\mathbf{v}^{(j,r)}(r,t) = \frac{\hbar}{2mi} \psi_{j}^{\dagger} \mathbf{V} \psi_{j}^{KS} - \mathbf{V} \psi_{j}^{KS} \psi_{j}^{\dagger} - \frac{e}{mc} \mathbf{A}(r,t), \quad (A18)$$

$$\mathbf{m}^{(j,r)}(r,t) = \psi_{j}^{\dagger} \mathbf{\sigma} \psi_{j}^{KS}. \quad (A19)$$

Finally, from Eq. (A15) the divergence of the spin current tensor may be rewritten as

$$-\mathbf{\nabla} \cdot \mathbf{J}_{KS}(r,t) = \frac{\hbar}{2\mathcal{F}m} \mathbf{\nabla} \cdot (\mathbf{n} \times \mathbf{s}) - \sum_{j \in \mathcal{O}} \sum_{l} \delta_{\mathbf{m}} [\mathbf{m}_{j}(r,t) \cdot \mathbf{v}_{j}^{\prime}(r,t)] - \frac{e}{mc} \sum_{j} \delta_{\mathbf{m}} [\mathbf{n} \mathbf{A}^{\prime}(r,t)] - \mathbf{\nabla} \cdot \mathcal{D}(r,t). \quad (A20)$$

Then, by substituting Eq. (A20) into Eq. (A5) we obtain

$$\frac{d}{dt} \mathbf{m}(r,t) = -\mathbf{\nabla} \cdot \mathcal{D}(r,t) - \sum_{j \in \mathcal{O}} \sum_{l} \delta_{\mathbf{m}} [\mathbf{m}_{j}(r,t) \cdot \mathbf{v}_{j}^{\prime}(r,t)] + \frac{\hbar}{2\mathcal{F}m} \mathbf{\nabla} \cdot (\mathbf{n} \times \mathbf{s}) + \mu_{B} \mathbf{n} \times \mathbf{B}_{XC}(r,t) + \mathbf{T}_{SO}(r,t). \quad (A21)$$

Finally, by decomposing the magnetization into its single-particle components $\mathbf{m}_{j}$ we can define the magnetization material derivative as

$$\frac{D}{Dt} \mathbf{m}(r,t) = \frac{d}{dt} \sum_{j \in \mathcal{O}} \mathbf{m}_{j}(r,t) + \sum_{j \in \mathcal{O}} (\mathbf{v}_{j} \cdot \mathbf{\nabla}) \mathbf{m}_{j}(r,t), \quad (A22)$$

with the spin continuity equation that becomes

$$\frac{D}{Dt} \mathbf{m}(r,t) = -\mathbf{\nabla} \cdot \mathcal{D}(r,t) - \sum_{j \in \mathcal{O}} \mathbf{\nabla} \cdot \mathbf{v}_{j}(r,t) \mathbf{m}_{j}(r,t) + \frac{\hbar}{2\mathcal{F}m} \mathbf{\nabla} \cdot (\mathbf{n} \times \mathbf{s}) + \mu_{B} \mathbf{n} \times \mathbf{B}_{XC}(r,t) + \mathbf{T}_{SO}(r,t) \quad (A23)$$

or

$$\frac{D}{Dt} \mathbf{m}(r,t) + \sum_{j \in \mathcal{O}} \mathbf{\nabla} \cdot \mathbf{v}_{j}(r,t) \mathbf{m}_{j}(r,t) = -\mathbf{\nabla} \cdot \mathcal{D}(r,t) + \mu_{B} \mathbf{m}(r,t) \times \mathbf{B}_{eff}(r,t) + \mathbf{T}_{SO}(r,t), \quad (A24)$$

where we have introduced an effective magnetic field

$$\mathbf{B}_{eff}[\mathbf{n}, \mathbf{s}](r,t) = \mathbf{B}_{XC}[\mathbf{n}, \mathbf{s}](r,t) + \frac{1}{e} \left[ \frac{\mathbf{n} \cdot \mathbf{s}}{n} + \mathbf{v}^{2} \mathbf{s} \right]. \quad (A25)$$

The continuity equation for the electron density instead follows immediately from Eq. (A4) through the definition of velocity field

$$\frac{Dn}{Dt} = -n \mathbf{\nabla} \cdot \mathbf{v}. \quad (A26)$$

It should be noted that the kinetic field $\frac{1}{e} \left[ \frac{\mathbf{v} \cdot \mathbf{v}}{2} + \mathbf{v}^{2} \mathbf{s} \right]$ written in Eq. (A25) is expressed in terms of the density and spin density, which are observables of the many-body system. This means that the kinetic field obtained within the Kohn-Sham formalism is identical to its many-body counterpart.
