This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the author guidelines.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the ethical guidelines, outlined in our author and reviewer resource centre, still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Fe(III)-doped coordination polymer of Mn$_{13}$-clusters with improved activity for oxygen reduction reaction

Tian Wen$^a$, Wolfgang Schmitt$^b$ and Lei Zhang$^a$

Fe(III) dopants have been introduced to a porous coordination polymer of Mn$_{13}$-clusters to form composite materials. The resulting Fe@Mn$_{13}$-polymer showed enhanced oxygen reduction reaction (ORR) activity, making it a low-cost and noble-metal-free ORR electrocatalyst.

The search for clean and renewable energy sources has attracted tremendous attention due to the ever-increasing consumption of fossil fuels and worldwide environmental crisis. New sustainable energy concepts rely on the fabrication of high-efficiency electrochemical energy storage and conversion devices and the development of oxygen reduction reaction (ORR) catalysts. To date, Pt-based ORR catalysts have been extensively explored and reveal the highest activity. However, the scarcity and high-cost of Pt materials have greatly limited their large-scale applications. Thus, it becomes desirable to develop alternative ORR catalysts of cheap and abundant transition metals. Among them, Fe is one of the most promising candidates and many Fe-based ORR catalysts have been reported. Although many progresses have been achieved, it still remains a challenge to improve the electrochemical activity and stability of Fe-based ORR catalysts.

The capacity and atomic utilization efficiency of catalysts are greatly influenced by their morphology and size. Accordingly, ultra-small nanoparticles or even single-atom Fe-catalysts have recently been investigated, achieving enhanced ORR activities. However, such atomic catalysts suffer from their strong tendency towards aggregation. To solve this problem, porous matrixes have been applied to support and stabilize the single-atom Fe-catalysts, including metal-organic frameworks (MOFs) and porous carbon frameworks. From the view of structural design, such porous materials can also provide a tool to further tune the activity of the designed complex catalysts beyond the role of support. Especially, additional functionality could be incorporated if the nodes of the porous matrixes were transition metal clusters, which themselves impart ORR activity.

Considering other earth-abundant catalysts, manganese oxide has also been confirmed to be a promising, non-noble metal ORR catalyst with high performance. Similarly, molecular oxide analogues, Mn-oxo clusters, should also have potential to reduce oxygen. Thus, the combination of Fe catalysts and Mn clusters within one ORR system might give rise promising synergistic advantages. Following this consideration, we applied a porous coordination polymer of Mn$_{13}$-oxo clusters to distribute and stabilize individual Fe(III) ions at molecular level and evaluate the ORR performance. Thus, the catalytic system distinguishes itself from bulk clusters or nanoparticles to form complex catalyst.

In our previous work, we employed a 1D Mn$_{13}$-polymer with distinctive pore diameters (ca. 10 \times 12 Å) to adsorb TCQN molecules and encapsulate CdS nanoparticles to enhance the photocatalytic H$_2$ production. Herein, taking advantage of the supramolecular channels of the Mn$_{13}$-polymer, we further introduced Fe(III) dopants into the Mn$_{13}$-oxo cluster-based framework via a two-step fabrication method to form Fe@Mn$_{13}$-polymer composites (Scheme 1). The obtained materials were characterized by several analytical methods including transmission electron microscopy (TEM), energy dispersive X-ray (EDX) spectra and the elemental mapping, and X-ray photoemission spectroscopy (XPS). Moreover, the obtained Fe@Mn$_{13}$-polymer displayed enhanced catalytic ORR activity in 0.1 M KOH solution.
Microcrystals of the Mn$_{13}$-polymer were synthesized via a reported solvothermal method. The freshly prepared Mn$_{13}$-polymers were then immersed into an aqueous solution of FeCl$_3$ for 24 hours as described in the experimental section (see ESI for details). Prior to the electocatalytic studies of the composite material, the structural attributes and stability of the prepared Fe@Mn$_{13}$-polymer was investigated. The powder X-ray diffraction (PXRD) analysis confirmed that the porous framework of the original Mn$_{13}$-polymer remained unchanged upon Fe$^{3+}$ uptake (Figure S1). Fourier transform infrared spectroscopy (FT-IR) was used to undoubtedly identify the presence of the organic ligands. The IR bands at ~982, 1100 and 2919 cm$^{-1}$ (Figure S2), originate from the bending vibrations of C–N, C–C moieties and from C–H stretching vibrations, respectively. Raman spectra also confirmed the presence of terminal tert-butylphosphonate ligands which resulted in signals at 960-990 cm$^{-1}$ (Figure S3). Furthermore, the solid-state UV-vis spectrum of original Mn$_{13}$-polymer exhibited two characteristic bands at 245 and 451 nm (Figure S4). However, the UV–vis spectrum of Fe@Mn$_{13}$-polymer showed a broad band between 200-600 nm, which might be attributed to charge transfer interactions between the Mn$_{13}$-polymer and Fe(III) dopants.

The morphology of the obtained Fe@Mn$_{13}$-polymer was characterized by scanning electron microscopy (SEM) and transmission electron microscopy (TEM). As shown in Figure 1a, after immobilization, the samples of Fe@Mn$_{13}$-polymer retain their well-defined crystalline morphology. The obtained TEM images were that of a homogeneous sample, indicating that there was no aggregation of bulk metal or oxide nanoparticles (Figure 1b). In addition, no lattice fringes of crystallized Fe or Mn oxides were detected by the high-resolution TEM (Figure 1c), further suggesting that the structure of the Mn$_{13}$-polymer was stable and no bulk metal oxides particles were formed during the Fe(III) ion absorption process. Moreover, results of energy dispersive X-ray (EDX) spectroscopy and the element mapping confirmed the homogeneous distribution of Fe dopants in the prepared Fe@Mn$_{13}$-polymer sample: (a) SEM, (b) TEM and (c) HRTEM images. (d) EDX spectrum and (e, f) elemental mapping.

To further analyze the composition and chemical states of the prepared Fe@Mn$_{13}$-polymer material, high resolution XPS studies were performed. The obtained spectra confirmed the presence of Fe, Mn, C, O, P, N and Cl elements (Figure 2a). As shown in Figure 2b, the XPS spectrum of the Mn 2p region presented two strong peaks at 652.9 and 642.3 eV, which can be assigned to Mn 2p1/2 and 2p3/2, respectively. The Fe 2p region showed two main peaks at 712.8 and 725.6 eV of Fe 2p3/2 and Fe 2p1/2 (Figure 2c), suggesting that the oxidation state of the Fe dopants in the Fe@Mn$_{13}$-polymer is +III. The O 1s spectrum can be divided into two peaks (Figure 2d), whereby one signal at 531.7 eV derives from P=O moieties and the one at 533.2 eV can be attributed to OH groups.

The above results demonstrated that the structure of the Mn$_{13}$-polymer remained almost unchanged after Fe(III) dopants were successfully introduced. Then the ORR activity of the prepared Fe@Mn$_{13}$-polymer was tested in an O$_2$ saturated 0.1M KOH solution using a rotating disk electrode set-up (Figure 3). The linear sweep voltammetry (LSV) results indicated that the Fe@Mn$_{13}$-polymer showed the best activity in terms of the most positive onset potential. As shown in Figure 3b, the E1/2 of the Fe@Mn$_{13}$-polymer was 0.70 V, which was 50 mV more positive than that of the pure Mn$_{13}$-polymer, highlighting the important role of Fe(III) dopants to improve the ORR activity. Also, the Tafel slope value of the Fe@Mn$_{13}$-polymer is 130 mV dec$^{-1}$, which is significantly smaller than 265 mV dec$^{-1}$ of the pure Mn$_{13}$-polymer (Figure S7), indicating better ORR activity. The electrochemical impedance spectroscopy (EIS) was also investigated to gain insights into charge transport processes that relate to the catalyst conductivity. The semicircular diameter in the EIS of the Fe@Mn$_{13}$-polymer is smaller than that of the unmodified Mn$_{13}$-polymer (Figure S8). On the other hand, the smaller charge transfer impedance implies better access of the O$_2$ containing electrolyte to the Fe@Mn$_{13}$-polymer surface and faster charge transfer on the surface and within the structure, in comparison to the native Mn$_{13}$-polymer, which is a direct result of the Fe-doping within the porous structure of Mn$_{13}$-polymer. On the other hand, the smaller semicircular diameter in the EIS of the Fe@Mn$_{13}$-polymer contributes to shuttle charges from the catalyst to the O$_2$ substrate, which increased ORR affections with a higher diffusion limiting current density. Thus, the synergistic effect of Fe dopants and Mn$_{13}$-polymer.

Figure 3. Linear sweep voltammetry (LSV) of Mn$_{13}$-polymer (Figure S1), Fe@Mn$_{13}$-polymer (Figure 1d-f, S1). Furthermore, the Fe(III) uptake was calculated to be ca. 0.45 wt% as determined by inductively coupled plasma-mass (ICP) spectrometry analysis.
resulted in improved ORR activity. Although the activity of the hybrid Fe@Mn\textsubscript{13}-polymer is lower than Pt/C (Figure S6), it is still of significance as a noble-metal-free ORR electrocatalyst.

To examine the fuel crossover effect, Fe@Mn\textsubscript{13}-polymer samples were cycled in both O\textsubscript{2}-saturated 0.1 M KOH and O\textsubscript{2}-saturated 0.1 M KOH + 1.0 M methanol solutions. There were no obvious changes of the current density in the presence of Fe@Mn\textsubscript{13}-polymer after injecting methanol into the solution (Figure 3a), demonstrating that the Fe@Mn\textsubscript{13}-polymer had excellent tolerance to methanol crossover. The applied Mn\textsubscript{13}-polymer contains rich tert-butylphosphonate ligands with hydrophobic-CH\textsubscript{3} group, endowing it with high aqueous stability. The Fe and Mn atoms in the hybrid Fe@Mn\textsubscript{13}-polymer are both alterable valent ions, possibly contributing to the electrochemical flexibility and stability. The stability and durability of the Fe@Mn\textsubscript{13}-polymer were then assessed by cycling tests between 0.6 and 1.0 V at a sweep rate of 50 mV s\textsuperscript{-1} in O\textsubscript{2}-saturated 0.1 M KOH. After 5000 continuous cycles (Figure 3d), only minor changes in E\textsubscript{1/2} (~1.5 mV) were observed. Moreover, after the CV tests, the LSV and IR spectra of Fe@Mn\textsubscript{13}-polymer were almost unchanged (Figure S1, S9).

In conclusion, for the first time, coordination polymers based on Mn-clusters have been applied as noble-metal-free ORR electrocatalysts. Taking the advantage of its porous structure, Fe(III) doped Mn\textsubscript{13}-polymer composite catalysts were synthesized and characterized. Electrochemical studies confirmed that the obtained Fe@Mn\textsubscript{13}-polymer revealed enhanced and stable ORR activity. Therefore, this work highlights the potential of Mn coordination clusters as low-cost ORR electrocatalysts and may open an avenue to cheaper and environmentally-friendly electrolysis.
